#### Abstract

3

This research introduces a 'Hydrogen Interconnector System' (HIS) as a novel method for transporting electrical energy over long distances. The system takes electricity from randed renewable energy assets, converts it to hydrogen in an electrolyser plant, transports hydrogen to the demand centre via pipeline, where it is reconverted to electricity in either a gas turbine or fuel cell plant. This paper evaluates the competitiveness of the technology with 10 High Voltage Direct Current (HVDC) systems, calculating the following techno-economic 11 indicators; Levelised Cost Of Electricity (LCOE) and Levelised Cost Of Storage (LCOS). The 12 results suggest that the LCOE of the HIS is competitive with HVDC for construction in 2050 with distance beyond 350km in case of all scenarios for a 1GW system. The LCOS is lower 14 than an HVDC system using large scale hydrogen storage in 6 out of 12 scenarios analysed, 15 including for construction from 2025. The HIS was also applied to three case studies, with 16 the results showing that the system outperforms HVDC from LCOS perspectives in all cases, 17 and has 15-20% lower investment costs in 2 studies analysed. 18

19 Keywords:

20 Hydrogen Interconnector System, Hydrogen Economy, High Voltage Direct Current

21 Systems, Techno-economic analysis, Levelised Cost of Electricity, Levelised Cost of Storage.

Abbreviations: **HIS** - Hydrogen Interconnector System; **HVAC** - High Voltage Alternating Current; **HVDC** - High Voltage Direct Current; **LCOE** - Levelised Cost of Electricity; **LCOS** - Levelised Cost of Storage; **PEM** - Proton Exchange Membrane; **FC** - Fuel Cell.

#### 1. Introduction

With an increasing recognition of the effects of climate change, countries have begun 23 implementing roadmaps outlining their approach to achieve net-zero targets. Increasing the 24 amount of renewable energy resources to replace fossil fuels is a key element of these policies, 25 with the United Kingdom (UK) targeting 40GW of offshore wind by 2030, and an additional 26 capacity of 35GW needed to achieve a zero carbon economy by 2050 [1] [2]. In addition to 27 more developed renewable technologies such as wind and solar, policy makers have identified 28 hydrogen as a key solution to decarbonise multiple sectors over time - the EU aims to meet 29 8-24% of total energy demand with hydrogen by 2050, equal to up to 2250TWh [3]. To 30 produce 'green' hydrogen (hydrogen produced by renewable resources), the European Union 31 (EU) aims to deploy at least 45GW of electrolysers powered by renewable electricity in the 32 next 30 years, producing up to 10 million tonnes of hydrogen. 33

To enable the widespread use of renewable hydrogen, it is essential that a hydrogen transportation infrastructure is developed. In the EU, 11 gas infrastructure companies have expressed their vision for a 'European Hydrogen Backbone', proposing the creation of a 23000km dedicated pipeline network by 2040 [4]. Similarly, the UK National Grid is exploring linking industrial clusters with a 2000km pipeline network built as early as 2030 [5]. These proposals are heavily influenced by the need to increase security of supply; with renewable resources rarely co-located with demand, a hydrogen network would allow the supply of green hydrogen to reach end users.

One option that could benefit from the deployment of a hydrogen network is the utilisation of hydrogen interconnectors to transport electrical energy over great distances. This has the potential not only to meet increased electricity demand, but also to further improve security of supply through the leveraging of hydrogen storage to compensate for the intermittent nature of renewable energy technologies, reducing the cost of renewable electricity to consumers.

This paper presents a model for a novel 'Hydrogen Interconnector System' (HIS), analysing
the techno-economics of the system from LCOE and LCOS perspectives. The lowest cost

HIS is first identified, and then compared to an equivalent HVDC system under different scenarios and sensitivities, and the model applied to three case studies to evaluate the system when used as an interconnector.

Existing research in the field of hydrogen includes studies in hydrogen production [6] [7] [8] and transmission network optimisation [9] [10] [11]. While studies in the economics of hydrogen transport do exist, there is general disagreement on how economical hydrogen pipelines are when compared to HVDC transmission [12] [9]. In addition, more accurate cost data has become available since their publication. This model aims to contribute to the research field by leveraging this data to analyse the costs of hydrogen transmission under different scenarios, enabling a comprehensive techno-economic comparison with HVDC, providing more insight into the feasibility of hydrogen interconnectors between 2020 and 2050.

It is to be noted that model for the HIS specifically generated techno-economic indicators
as outputs to be analysed and compared to HVDC. The calculations mentioned in Section
4 do not capture the system dynamics and its precise operation, as well as the interactions
that the HIS could have with surrounding energy systems.

# 66 2. State of the Art

# 67 2.1. Hydrogen Pipelines

gas pipelines [15]:

75

76

Despite hydrogen pipelines being in use for almost a century, there are currently only
4500km of hydrogen pipelines globally, compared to over 160000km of oil and gas pipelines
[13] [14]. As such, research into hydrogen pipeline technology is relatively scarce compared
with other pipeline transportation methods. Transmission of gaseous hydrogen via pipeline
has many similarities with that of natural gas: following this, most literature investigates
how the differences between hydrogen and methane translate to pipeline design and cost.

From a technical perspective, four main differences exist between hydrogen and natural

• The volumetric energy density of hydrogen is 1/3 that of methane

- Hydrogen embrittlement of steel must be accounted for in pipeline design
- Compression has higher capital and operational costs for hydrogen systems
- High pipeline utilisation is required for economic feasibility

Each of these factors require adjustments to be made to traditional natural gas pipeline designs, which commonly result in higher construction costs [16].

Due to the lower energy density of hydrogen compared to methane, hydrogen pipelines require larger capacities than natural gas pipelines to transport the same amount of energy [17] [9]. This would be achieved either through compressing the hydrogen to higher inlet pressures or designing pipelines with larger internal diameters. Most hydrogen transmission pipeline designs have typical operating pressures of up to 10MPa and internal diameters of 50-120cm, with some concepts having pressures of up to 100MPa [10] [18] [19].

Hydrogen embrittlement is a key constraint in hydrogen pipeline design, particularly 88 in the choice of materials and pipe wall thickness [20]. Higher strength steels are desirable 89 when considering pipeline economics - with materials comprising 26% of natural gas pipeline 90 costs, lower wall thicknesses have the potential to drastically reduce total costs while main-91 taining safety standards. However, higher strength steel is more susceptible to hydrogen 92 embrittlement, a process where metals become brittle due to the diffusion of hydrogen into 93 the material [21]. As such, the majority of current hydrogen pipeline projects use of low strength steels with large thicknesses, following ASME B31.12 codes, resulting in a material cost several times that of natural gas [22] [23]. 96

In terms of storage of gaseous hydrogen, the main forms currently discussed in literature are salt cavern storage and compressed storage in pressurised tanks. Both methods are proposed for utilisation alongside long distance hydrogen transmission pipelines, enabling storage in the region of PWh [24]. However, for the purposes of providing smaller scale storage capacity, 'linepacking' can be used within pipelines. This has the potential to enable firming of renewable supply, potentially reducing prices within the wholesale electricity market [25]. While the benefits of such a storage medium have been discussed in existing literature, no existing research investigates the quantitative benefits from a LCOS perspective.

# 106 2.2. Hydrogen Transmission Networks

107

108

109

110

111

The majority of current literature relating to the development and construction of a hydrogen pipeline infrastructure focuses on the design and optimisation of hydrogen transmission networks [9] [10] [11]. They rely on pipeline cost equations generated by [16] and [26] to optimise the cost and capacity of a network, calculating the optimal pipeline diameter, length and location to achieve a given demand while minimising cost.

While these studies provide useful insight into the ideal location of hydrogen transmission 112 infrastructure, they have some key shortcomings. Firstly, the total cost of the designed systems are not investigated in great detail, providing scope to further investigate the techno-114 economics of hydrogen pipeline transmission. Secondly, the majority of these models do not 115 consider the production method of hydrogen. Despite 95% of hydrogen currently being 116 produced from fossil fuels, all hydrogen roadmaps cite electrolysis as the main technology to 117 be used to scale production [3] [27]. Following this, there is significant scope to incorporate 118 hydrogen production into the techno-economics of a 'green' hydrogen transmission system, 119 to provide a clearer picture of the levelised costs of future projects. Of existing literature covering the optimisation of hydrogen transmission networks, one piece of research considers 121 whether to transport energy as hydrogen or as electricity, with the aim being to minimise 122 the total cost of network while meeting transport demand in the UK [28]. The research 123 indicates that all of the UK's transport demand can be met with onshore wind through 124 deployment of a hydrogen + electricity network. Due to the uncertainty of input data 125 regarding electrolyser/fuel cell costs, sensitivity analyses are recommended as a future step 126 to improve upon the research. In addition, the research only considers compressed and underground hydrogen storage, and recommends investigation into pipeline storage as a 128 means to further develop a hydrogen transmission model.

# $^{30}$ 2.3. Techno-Economic Analysis of Electrical Energy Transmission

The state of the art methods for analysis and optimisation of energy infrastructure are techno-economic indicators, namely LCOE and LCOS [29]. These indicators enable an economic comparison to be made between different technologies for the purpose of electrical energy transport and storage respectively.

Some literature does exist which compares the techno-economics of hydrogen pipelines 135 and HVAC/HVDC transmission [9] [12] [30]. These compare the LCOE of each technology, 136 based on the costs of construction, operation and maintenance, and additional factors. There 137 is some disagreement on which system is the most economical for electricity transport, with [12] suggesting a pipeline system is less expensive then HVDC at distances larger 139 than 740km, while [9] finds that HVDC transmission delivers a LCOE 0.08-0.12 \$/kWh 140 less than hydrogen pipelines, for the case of transmission from North Dakota to Chicago 141 (1600km). Further research into the cost of a hydrogen pipeline system would be beneficial 142 to provide more insight into the economic benefits relative to HVDC. In addition, there are 143 various considerations which these existing studies do not include. Incorporation of learning 144 curves of electrolysers, onshore/offshore configurations and more accurate cost data could significantly improve upon these models, providing a more accurate picture of the cost of a hydrogen pipeline interconnector. Furthermore, as mentioned in [28], sensitivity analysis 147 and research into the storage benefits of hydrogen pipelines would be useful when comparing the effectiveness of such a system with HVDC counterparts.

# 3. Hydrogen Interconnector Model

This section presents the technical model of the HIS, describing the main components of the system and its operation.

# 3.1. System Overview

131

132

133

134

The HIS enables electrical energy to be transported from stranded renewable resources to areas of large demand, while providing embedded storage to account for intra-day and

seasonal imbalances between supply and demand. The system operates by converting electricity to gaseous hydrogen at the source, pressurising the hydrogen and transmitting it along long distances via a pipeline, where it is reconverted back to electricity at the centre of demand. Storage is provided as linepack within the pipeline. This system is intended to be used to transport electricity in the region of MWs to GWs, similar to that of current high voltage transmission lines.

Figure 1 provides a high level schematic of the system, and Table 1 highlights the main technical elements of the system.

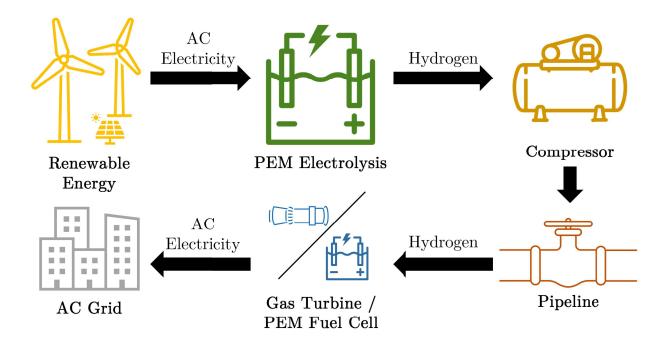

Figure 1: Schematic of HIS, including connections to energy source and grid.

#### 3.2. Hydrogen Generation from Electricity

164

165

166

167

168

To convert energy generated from wind or solar sources to hydrogen, the electricity is used to split water into hydrogen and oxygen. This occurs at an electrolyser plant, which is assumed to be able to convert up to 2GW of input electricity into hydrogen. However, the largest electrolyser plants that currently exist have capacities of up to 20MW [27]. As such, this model considers a PEM electrolyser plant - despite currently having low capacities, PEM

systems can be modularly 'stacked' to achieve the desired scale, without impacting efficiency or output pressure [27]. In addition, the technology is less mature than conventionally used alkaline electrolysis; as such production is expected to increase to GW scale in the future. PEM electrolysers are also highly flexible systems, enabling operation ranges from zero load to 160% capacity, making it suitable for an intermittent input.

The electrolyser plant takes DC electricity at input provided by an AC/DC converter at the energy source, and requires 9L of feedstock water to produce 1kg hydrogen gas [27]. PEM systems output high purity hydrogen at pressures of between 3 and 6 MPa, so a compressor is required to increase the pressure to 10-20MPa at pipeline inlet, depending on the required flow rate in the pipeline. Centrifugal compressors are commonly used in natural gas pipelines, and so are considered in this model [17]. Following [31], an allowable pressure ratio per compressor stage of 2:1 is assumed, resulting in 2-4 stages required in the system.

## 3.3. Hydrogen Transmission and Storage

Flow of hydrogen is enabled through the pressure loss between inlet and outlet of the hydrogen pipeline, which is intended to be broadly similar to that of a natural gas pipeline, with slight adjustments made to account for leakage and embrittlement. The pipeline is constructed of API 5L Grade X52 carbon steel, and internal diameter of 50-120cm. The pipeline delivers hydrogen at an outlet pressure of 3.55MPa, and the inlet pressure is varied to achieve the desired flow rate of the system.

To enable storage within the pipeline, it is assumed that the operating pressure of the pipeline can be reduced by as much as 25% up to 2 times a day, enabling energy to be stored and released on a daily or seasonal timescale.

# 3.4. Conversion of Hydrogen to Electricity

193

Two technologies are considered in the interconnector model for the purpose of reconverting hydrogen to electricity: hydrogen-fired gas turbines (H2GT) and PEM fuel cells (PEMFC).

In the H2GT, the hydrogen is ignited and expanded to drive a generator, outputting AC electricity. It is assumed that multiple turbines operate in parallel - a base size of 50-100MW is assumed, with the total number of turbines depending on the size of the system. There are few H2GTs in operation today, however the same technology as natural gas-fired combined cycle gas turbines can be used with hydrogen, giving confidence that such a system could be achieved [32].

As with the electrolysis plant, the fuel cell system will consist of multiple H2GTs, as-

As with the electrolysis plant, the fuel cell system will consist of multiple H2GTs, assuming they can be modularly 'stacked' to produce a large scale plant. The system outputs DC electricity, and as such will require a DC-AC converter to provide AC electricity to end users.

Table 1: Technical Overview of Hydrogen Interconnector Model

| Delivered Power                             | 50-4000MW          |
|---|--------------------|
| Length                                      | 50-2500km          |
| System Lifetime                             | 40 years           |
| Efficiency                                  | 24.1-48.6%         |
| H <sub>2</sub> to e <sup>-</sup> Conversion | H2GT / Fuel Cell   |
| Pipeline Diameter                           | 50-120cm           |
| Pipeline Configuration                      | Onshore / Offshore |

# $^{57}$ 4. Methodology

LCOE method was used to evaluate costs of the HIS, and compare it with the equivalent HVDC system in the context of transporting electricity. The simplified LCOE equation is shown in Equation 1. This equation was broken down into lifetime Capital Expenditure (CAPEX) and Operating Expenditure (OPEX), which was annualised to each year t. A discount rate, i is applied to both the OPEX and electricity output  $Q_{el}$  to account for the investment cost over the lifetime n. The full equation is given in Equation 2. This equation was used to calculate LCOS by taking  $Q_{el}$  as the annual electricity discharged by the system following [33]. In all calculations, a value of i of 3% was used, corresponding to a 'stable

market environment with high investment security' as specified by the International Energy Agency [34].

$$LCOE = \frac{Sum \text{ of Costs Over Lifetime}}{Sum \text{ of Electrical Energy Produced Over Lifetime}}$$
 (1)

$$LCOE = \frac{CAPEX + \sum_{t=1}^{n} \frac{OPEX_t}{(1+i)^t}}{\sum_{t=1}^{n} \frac{Q_{el}}{(1+i)^t}}$$
(2)

The breakdown of CAPEX and OPEX is shown in Equations 3 and 4. The CAPEX takes into account the total initial investment for the system  $C_{inv}$  and the total replacement costs over the system lifetime  $C_{repl,t}$ . The total OPEX is comprised of the total Operating and Maintenance (O&M) costs for all system components, and the cost of electricity at the electrolyser and compressor  $E_c$ .

$$CAPEX = C_{inv} + C_{renl.t} \tag{3}$$

$$OPEX = O\&M + E_c \tag{4}$$

All of the components considered in the model besides the compressor are considered to 223 be in early market stages, meaning that technical and cost advancements are expected in the future. In particular, the technical capabilities, costs and scalability of PEM electrolysers 225 and PEMFCs are expected to drastically improve over time according to existing road maps 226 and research [2] [27]. Furthermore, few hydrogen pipelines are in operation today, with up to 20000km of additional capacity expected to be built in mainland Europe [4]. This may result in decreasing pipeline costs as production increases. In addition, renewable energy 229 technologies are still decreasing in price: in the case of onshore wind, agreed strike prices of 230 as low as 2¢ per kWh are predicted for 2050 [35]. 231 Following the importance of these changes and uncertainty about future costs, data from 232 various roadmaps and research was gathered and incorporated into the model to produce 233 levelised costs for three scenarios: 'high' (most optimistic), 'medium' (base level), and 'low'

(least optimistic), with each scenario applied to a construction year in 2020, 2025, 2030 and 2050, generating a total of 3 input data sets.

The data set for the 'medium' scenario is shown in Table 2, with all financial data adjusted to  $\$_{2020}$ . All 3 scenario data sets are given in the Appendix. Sections 4.1 to 4.4 detail the key financial and technical considerations for each element of the system that contribute to the the levelised cost calculations and scenarios.

Table 2: Medium Scenario Data Set

|                                   | 2020  | 2025  | 2030  | 2050   |

# 4.1. Electrolyser

259

260

262

The initial capital cost of the PEM electrolysis plant was considered based on the cost per 242 kW of input electricity, with data sourced from the International Energy Agency 'Future of Hydrogen' report [27]. The decrease in CAPEX of the electrolyser is expected to be 244 driven primarily by the scaling up of production over time, resulting in learning rate effects. 245 The operating lifetime of the system was taken as the lifetime of the electrolyser stack, with technological improvements in the stack increasing the durability of the electrolyser over time. Following this, it was assumed that at end of life, a complete replacement was 248 not necessary. Instead, the replacement cost was taken as the % of CAPEX required to 249 replace and/or repair the electrolyser stack, with this value decreasing over time in line with improvements in resiliency. The total replacement cost was calculated based on the 251 CAPEX/kW for each replacement year, interpolating between data provided for 2020-2050. 252 The OPEX of the electrolyser was comprised of the cost of input electricity, feedstock 253 water and O&M costs. The cost of water was taken as a fixed \$1.60 per m<sup>3</sup> in all scenarios 254 [27]. The electricity cost was taken from data provided by the IRENA 'Future of Wind' 255 report [35] for onshore and offshore wind energy prices. Changes in the LCOE of wind were 256 taken into account across the lifetime of the system, assuming that the costs do not decrease 257 beyond 2050. 258

Technological improvements were expected to result in increasing the maximum output pressure of the electrolyser. This value was taken into account to create 'compressorless' scenarios, where the electrolyser can achieve the desired pressure at inlet to the pipeline without the need for additional compression.

### 4.2. Compressor

In cases where pressurisation was required at the pipeline inlet, the CAPEX and OPEX of the compressor were added to the LCOE calculation.

Compressor CAPEX is directly related to the power required at the shaft to pressurise incoming hydrogen, as shown in Equation 5 [40].

$$P = Q * \frac{ZTR}{M\eta} * \frac{N\gamma}{\gamma - 1} * \left(\frac{P_{out}}{P_{in}}^{\frac{\gamma - 1}{N\gamma}} - 1\right)$$
 (5)

The equation calculates the required shaft power P for a compressor with N stages, 268 to achieve an increase between the pressure at inlet  $P_{in}$  and outlet  $P_{out}$ , considering the incoming flow rate Q, compressibility Z, and molecular mass M of hydrogen. Constants 270  $\gamma$  and R are the ratio of specific heat (1.4) and the universal ideal gas constant (8.314) 271  $\frac{J}{molK}$ ) respectively. The inlet temperature T was taken as 298.15K, corresponding to the 272 outlet pressure of the electrolysis plant. The power required is scaled by the efficiency of the compressor  $\eta$ , taken to be 88% [31]. The value of P was used as an input to each of 274 the equations given in [4] [19] [11] and [31] - which approximate the electrolyser CAPEX 275 based on power required - and then averaged to give a final CAPEX value. translated to an electrolyser CAPEX by taking an average of the cost equations given in

# 278 4.3. Pipeline

279

The construction cost of a natural gas pipeline can be separated into the following factors:

- Materials
- 281 Labour
- Miscellaneous
- Right of Way

Miscellaneous costs refer to regulatory filing fees, administration and overhead, surveying, supervision, contingencies and allowances for construction funds [16]. Parker [16] has created component-wise cost equations by plotting the costs of existing natural gas pipeline projects in the United States against a construction factor, and fitting a line of best fit to the data.

This produces a set of cost equations as a function of diameter and length. These equations
have been used to calculate the total CAPEX of the hydrogen gas pipeline, increasing the
cost of materials by 50% to account for greater wall thicknesses to reduce embrittlement,
and increasing labour costs by 25% due to the assumed higher weld costs to reduce leakage.

The O&M cost is expected to comprise predominantly of the cost of 'pigging' the pipeline
to identify leaks and defects.

Learning rates have also been applied to the material and labour costs at a decrease 8 294 and 14.2% respectively per doubling of pipeline production [20]. The increase in pipeline production was calculated assuming the growth of the EU Hydrogen Backbone reflects the 296 increase in global capacity of hydrogen pipelines. Data on the total length of the network 297 is available up to 2040 - it has been assumed that 50% of the network will consists of novel hydrogen pipelines. The 'medium' scenario assumes network construction ceases at 2040, 299 and the 'high' scenario assumes continued growth in the network until 2050. The 'low' 300 scenario assumes that no such network will be built, with no learning rate applied to the 301 pipeline costs. 302

# $_{603}$ 4.4. $H_{2}$ to Electricity Conversion

304

305

306

308

309

The costs of a H2GT are sourced from [32], with a CAPEX/kW of output electricity considered, and the OPEX consisting of fixed and variable O&M costs. The data is provided under First, Second and Nth Of A Kind scenarios (FOAK, SOAK, NOAK) which are translated directly into the costs for 2020, 2030 and 2050. These are small cost improvements relative to other components in the model, as the technology broadly follows that of conventional gas turbines, which are a mature technology.

Economic and technical inputs for the PEMFC broadly share the same approach with the PEM electrolyser plant. Costs are taken from the Fuel Cells and Hydrogen Joint Undertaking report, which provides estimations for capital costs of PEMFCs for 2020 through to 2030 [38]. The CAPEX/kW of output electricity is higher than that of the electrolyser in all scenarios due to the relative infancy of large scale stationary PEMFC technology. To fit the data to

2050, it was assumed that the costs continue to decrease at the same rate between 2030 and 2050 for all scenarios, resulting in costs which are nearly identical with the electrolyser.

Given the similarity in technology, the stack lifetime, OPEX and replacement costs (as a % of CAPEX) are taken to be identical to that of the electrolyser.

# 319 4.5. HVDC System

To compare the levelised costs of the HIS with HVDC, a model was created which achieves the same electricity output over an equivalent distance, excluding the additional storage capability of the pipeline. The model consists of two ±300kV cables connecting the output of the renewable energy source to the demand centre, reconverting the DC electricity to AC via a grid scale converter. Costs for the cable and converter have been sourced from the RealiseGrid review of costs of transmission infrastructures, with data sourced for overhead, underground and sub-sea configurations [39]. Given the maturity of the technology, no cost or technology improvements with time have been considered.

To enable the HIS and HVDC systems to be compared from a LCOS perspective, it was 328 necessary to include the costs of an additional storage system within the HVDC system, as 329 an HVDC line lacks any form of embedded storage. As such, the costs of storing energy in 330 the form of hydrogen were added to the costs of the HVDC system. The storage system 331 considered consists of an electrolyser plant, compressor and salt cavern storage, with a gas 332 turbine used at the outlet of the salt cavern to release the stored energy as electricity. 333 Therefore, all costs and technical data used in the LCOS calculation are identical to that of Table 2, except for the cost of salt cavern storage, which was assumed to be 0.3 \$\frac{1}{2}kWh of 335 stored energy, following [33]. 336

#### 5. Results and Discussion

## 338 5.1. LCOE Analysis

337

Figure 2 shows the LCOE for each scenario, based on construction years in 2020, 2025, 2030 and 2050. The LCOE has been calculated for the base case of an onshore HIS delivering 1GW of electricity to the grid, at a distance of 100km between an onshore wind energy source

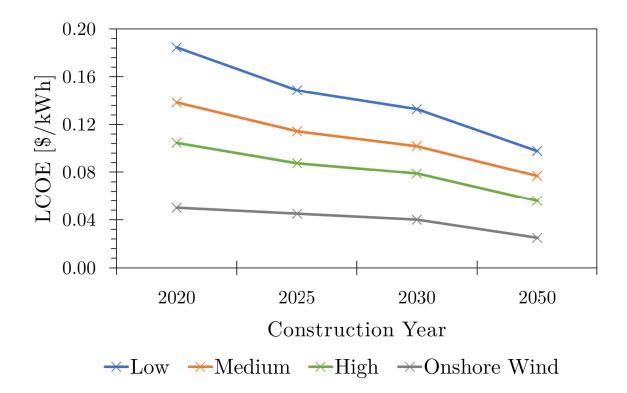

Figure 2: LCOE of 1GW/100km HIS (with H2GT) in comparison with cost of onshore wind.

and demand. The system consists of a 100cm diameter pipeline, with a H2GT connected to the pipeline outlet to generate AC electricity.

The LCOE ranges from 0.105 to 0.184 \$/kWh for construction in 2020, with the lowest cost range at 0.056 to 0.098 \$/kWh for construction in 2050.

Figure 3 provides a breakdown of the LCOE into its CAPEX and OPEX components. The LCOE of the system over its lifetime is dominated by the cost of input electricity, contributing 75 to 80% to the total value in all scenarios. This is due to the low efficiency of the system in all cases, resulting in between 2 and 4 times the amount of electricity delivered at output being demanded at input to the electrolyser. Following this, the main driver of the decrease in LCOE over time is the improvement in electrolyser efficiency, which increases the total system efficiency from 32.4 to 48.4% in the case of the 'medium' scenario, reducing the lifetime electricity demand by a 30%. This combined with the decrease in cost of onshore electricity from wind (as shown in Figure 2) results in lower operating costs for

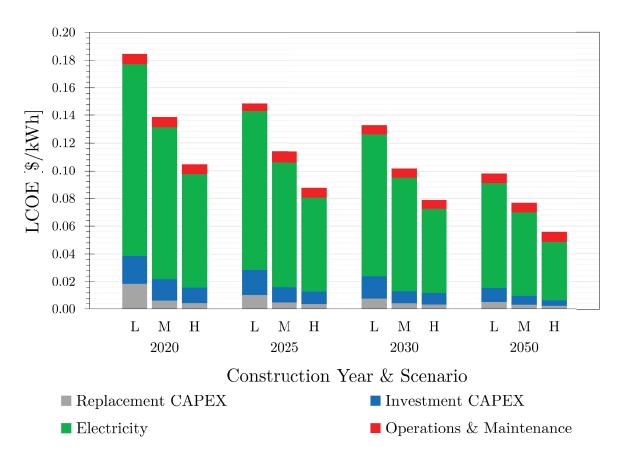

Figure 3: LCOE breakdown of  $1\,\mathrm{GW}/100\,\mathrm{km}$  HIS (with H2GT).

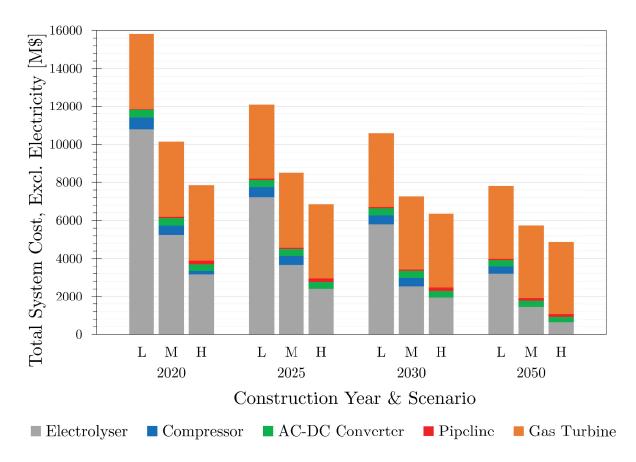

Figure 4: Composition of total system cost of 1GW/100km HIS (with H2GT, excluding electricity costs).

the electrolyser and compressor. 355

356

357

358

359

361

362

363

364

365

Figure 4 shows the total cost of the HIS excluding the cost of electricity, presenting the cost contributions of each component. The graph shows that the reduction in total cost is driven mainly by the decrease in costs of the electrolyser. This in turn is most affected by the lowering of CAPEX/kW of the component, decreasing by an average of 64.3% between 2020 and 2050 across the three scenarios. In addition, the lifetime of the electrolyser is predicted to more than double by 2050, and the stack replacement cost (as % of CAPEX) is expected to decrease by 20%. The combination of these factors results in the electrolyser shifting from being the main contributor to the total system cost for construction in 2020 and 2025 to contributing as low as 14% of the total cost in 2050 in the 'low' scenario.

The pipeline has a relatively low contribution to the CAPEX of the system, at <2%across all scenarios. This would suggest that longer pipeline distances could be more eco-366

nomically viable for the system, which is considered in more detail in Section 5.2. Similarly, 367 the compressor contributes only 3\% to the system CAPEX in 2020, with the contribution 368 decreasing to zero in 2050, due to the improvements in electrolyser output pressure remov-369 ing the requirement for a compressor. This suggests that while a compressorless HIS is 370 possible in the long term with the increased maximum output pressure of PEM electrolysis, 371 the improvements are minimal when considering the economics of the system. Instead, the 372 main benefits of compressorless systems are likely to be the improvement in overall system 373 efficiency and reliability. 374

Figure 4 also shows the increase in cost contribution of the H2GT to the total cost of the system over time. Given that the component has minimal cost improvements over time, the contribution becomes more significant, contributing up to 83% of the total costs in 2050, demonstrating that the H2GT is likely to be the greatest obstacle to cost competitiveness of the HIS.

375

376

377

378

379

With the H2GT making such a significant contribution to the total cost of the system in 380 later construction years, it is therefore necessary to compare the LCOE of the H2GT system 381 to that of a system using PEMFCs in combination with grid scale converters to generate 382 AC electricity from hydrogen flow. Despite currently having 4x higher capital costs and 383 14% lower efficiency when compared with a H2GT, PEMFCs have significant technology 384 and cost improvements expected over time - in contrast with the H2GT system. Figure 5 385 shows the difference in LCOE between the cost of a H2GT and PEMFC system. On average 386 across the three scenarios, the LCOE is 28% higher for construction in 2020, and 17% 387 higher in 2025. This is due in part to the higher CAPEX/kW of the PEMFC system, but is 388 mainly due to the efficiency being 10 to 15% lower than the H2GT: the lower efficiency when 389 generating electricity from hydrogen results in more electricity demanded at the electrolyser 390 to achieve the same 1GW capacity, significantly increasing electricity costs to the system 391 when a PEMFC is used. This is compounded by the higher cost of electricity from onshore 392 wind in 2020 and 2025. In these construction years, the lower replacement cost of PEMFCs compared with GTs is not sufficient enough to offset the increase in initial capital cost and 394 electricity demand at input. However the improvements in efficiency, replacement cost and 395

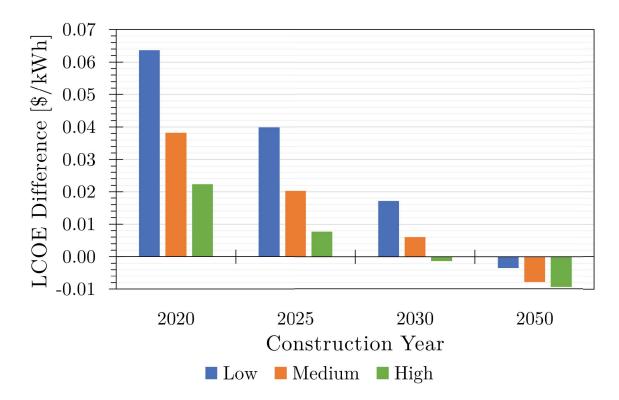

Figure 5: Comparison of LCOE with H2GT, Fuel Cell cheapest option.

lifetime of the PEMFC system means that the LCOE approximately reaches parity with that of the H2GT system in 2030 at 6% higher average LCOE, and a 0.1 ¢/kWh lower cost in the 'high' scenario. This trend continues into 2050, with LCOE becoming 0.3 - 0.9 ¢/kWh lower than the H2GT.

Overall, the most cost competitive HIS would consist of a H2GT in the short to medium term, with PEMFCs becoming the more desirable option in 2050. Therefore, the following cost-distance and LCOS analyses are carried out considering the HIS constructed with a H2GT in 2020 to 2030, with a PEMFC and converter used for construction in 2050.

# 5.2. LCOE-Distance Sensitivity

400

401

402

405

406

407

As shown in Section 4, the overall efficiency of the HVDC system is over 90%, which is between 40 and 65% higher than that of the HIS. The data presented in Figure 5 suggests that the HIS may only be competitive with HVDC for construction in 2050. Under this configuration, the lower CAPEX of the electrolyser and PEMFC, as well as high efficiency

could reduce the LCOE of the HIS sufficiently to compete with HVDC cables, which are less cost sensitive to the system capacity. This scenario is the focus of the LCOE-distance sensitivity analysis in this section.

Figure 6 describes the sensitivity of LCOE to distance in the case of a 1GW system 412 with a pipeline diameter of 100cm, constructed in 2050, comparing the PEMFC system to that of an HVDC underground system. When purely considering the usage of the system 414 to transport electricity, the HIS system could not achieve cost parity for distance up to 415 2000km. However, it is important to note that the comparison of LCOE does not take into 416 account the added benefit of embedded storage within the pipeline. Figure 6 also shows the LCOE-distance sensitivity of an HVDC system with the same amount of storage as the 418 HIS, assuming the pipeline can discharge to 90% of initial pressure every 2 days. The HIS 419 reaches cost parity with the HVDC system at distances <350km across all scenarios. This demonstrates the potential of the HIS to act as a low cost, large capacity storage system while delivering energy across long distances, which is investigated in the next section. 422

# 423 5.3. LCOS Analysis

Figure 7 shows the LCOS of all scenarios for the base case of a 1GW/100km system, based 424 on a pipe diameter of 120cm. Energy is discharged once a day by decreasing the average 425 pipeline pressure to 75% of normal (approximately 10MPa to 7.5MPa), corresponding to a 426 storage capacity of 2GWh. This corresponds to usage of the system as a 'short duration' 427 means of storage, with 365 cycles per year. The LCOS of the system decreases from an 428 average of 0.732 \$/kWh in 2020 to 0.398 \$/kWh in 2050. The total costs of the system are identical to that used in the LCOE calculation, therefore the drivers behind the decrease 430 in LCOS with time are the same as in Section 5.1, with the efficiency improvements of the 431 electrolyser and reduction in cost of electricity reducing total costs by the greatest amount. The usage of the PEMFC in 2050 results in a slightly higher efficiency for conversion to 433 electricity, meaning that the amount of electricity discharged per cycle increases, improving 434 the LCOS reduction.

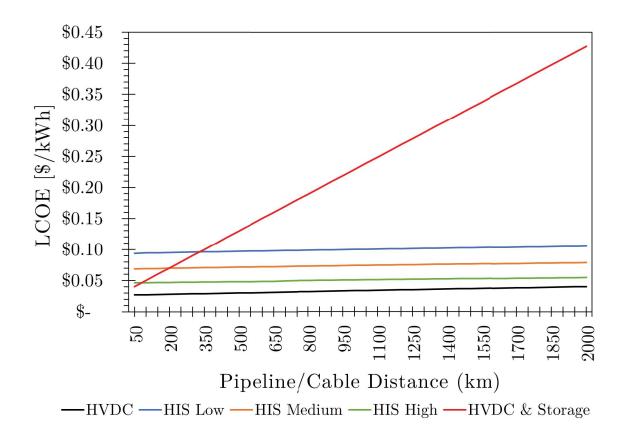

Figure 6: Sensitivity of LCOE with distance for a 1GW system, constructed in 2050. HIS and HVDC underground compared.

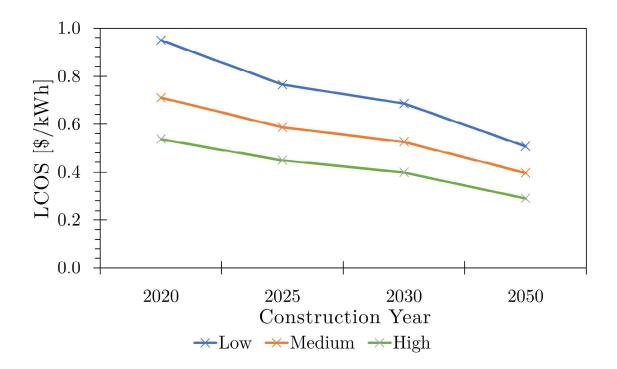

Figure 7: LCOS of 1GW/100km HIS.

[33] provides LCOS data for 'short duration' storage technologies for 2030, which are 436 compared below. The LCOS of the HIS system in 2030 is between 0.398 and 0.685 \$/kWh, 437 compared to a LCOS for a range of battery technologies of 0.19 to 0.22 \$\frac{1}{k}Wh, suggesting 438 the system will not be competitive with battery technologies from a storage perspective. However, these results suggest that the HIS may be competitive with alternate gaseous stor-440 age methods: [33] gives a LCOS of natural gas storage of 0.40 \$/kWh, which is higher than 441 that of the HIS when considering the more optimistic 'high' scenario. Further investigation into discharge rates, storage use case and effect of discharging on hydrogen embrittlement 443 would be beneficial to more accurately compare storage capabilities of the HIS with these 444 technologies. 445

Figure 8 shows the difference in LCOS between the HIS and HVDC + storage system.

The LCOS of the HIS is between 0.011 and 0.515 \$/kWh higher in 2020, with costs becoming

much more competitive in 2020 at 0.044 \$/kWh higher in the 'medium' scenario, and 0.115

\$/kWh lower in the 'high' scenario. This trend continues into 2030, with the 'medium'

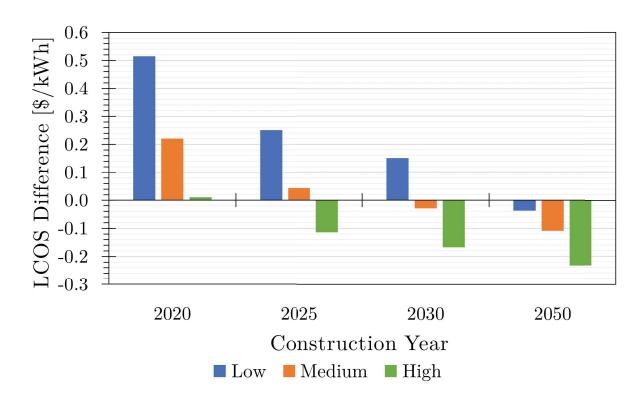

Figure 8: LCOS difference between HVDC+storage and HIS, HIS cheapest option.

scenario having a lower LCOS in addition to the 'high' scenario, and in 2050 the HIS has a competitive LCOS in all scenarios, at between 4 and 33% lower than the HVDC + storage system. Overall these results shows that despite the lack of competitiveness when solely considering electricity delivery, HIS would be a more attractive system than an HVDC system from a storage perspective from as early as 2025.

# 55 6. Case Studies

In this section, the HIS model is applied to three case studies, in order to demonstrate
the 'variety of use' cases for the system. Each example has a unique set of requirements for
the system including: input electricity source, pipeline configuration and length, and system
capacity. Inputs to the model have been adjusted to account for these differences. The
following main techno-economic outputs have been generated to evaluate the feasibility of
each case; LCOE, LCOS, and total investment cost. In addition, each case study is compared

with an equivalent HVDC system from a techno-economic perspective, and discussed in the
context of each specific use case. A summary of the input/output data for all case studies is
given in Table 3, with all costs in \$2020, calculated for construction in 2030. Maps highlighting
the pipeline route and key points can be found in the Appendix.

Table 3: Inputs and outputs for case studies

| Case Study                             | 6.1   | 6.2   | 6.3   |
|--|-------|-------|-------|
| Inputs                                 |       |       |       |
| Capacity (MW)                          | 500   | 4000  | 1500  |
| Total Length (km)                      | 127   | 810   | 2500  |
| Pipeline Diameter (cm)                 | 120   | 50    | 50    |
| Storage Discharge %                    | 99%   | 75%   | 90%   |
| Charge/Discharge Rate (cycles/day)     | 20    | 0.5   | 1     |
| HIS Outputs                            |       |       |       |
| Initial Investment Cost (M\$)          | 4047  | 9490  | 14728 |
| LCOE (\$/kWh)                          | 0.078 | 0.150 | 0.180 |
| LCOS (\$/kWh)                          | 0.446 | 0.482 | 0.192 |
| HVDC System Outputs                    |       |       |       |
| Initial Investment Cost (Actual) (M\$) | 281   | _     | -     |
| Initial Investment Cost (Model) (M\$)  | 537   | 11821 | 17363 |
| LCOE (\$/kWh)                          | 0.033 | 0.063 | 0.086 |
| LCOS (\$/kWh)                          | 0.803 | 0.528 | 0.799 |

# 466 6.1. Moyle Interconnector

The HVDC Moyle interconnector provides a bi-directional link between the electricity systems in Ireland and Great Britain, carrying 500MW across the 64km distance between coasts [41]. The system consists of a 63km HVAC overhead line between the National Grid and Auchencrosh on the coast of Scotland, AC-DC conversion, transmission via  $2x \pm 250$ kV subsea DC cables, and reconversion to AC at Northern Ireland. There have been significant

changes since its construction in 2002: increased grid penetration of renewable technologies and new market mechanisms such as intra-day trading have resulted in the system becoming increasingly outdated. In addition, due to grid constraints at either side, the system flow has been limited to 400MW. Following this, a major refurbishment project is underway to extract more performance from the system.

This case study investigates the prospect of using a HIS to transport electricity between 477 the two islands as an alternative to the existing HVDC system. The main benefit of using 478 the system over HVDC is the embedded storage within the pipeline: seasonal and intra-day 479 storage would enable increased renewable supply to the link while increasing the potential 480 capacity. Furthermore, the need for frequency support could be reduced if the linepack is 481 charged and discharged at a high frequency. These factors would increase utilisation of the 482 link, and reduce costs of intermittent renewable energy by allowing 'firming' of renewable 483 energy prices during trading. 484

The proposed hydrogen interconnector consists of a 127km pipeline (64km onshore + 63km subsea), with a combined electrolyser/H2GT plant located at either end to enable bidirectional transport. A 120cm diameter pipe is used to maximise storage capacity, and it is assumed that storage capacity is used primarily for frequency support, with 20 discharge cycles a day to 99% of initial pressure.

The initial investment cost and LCOE of the system is 7.5x higher than the equivalent HVDC system, however the majority of the cost difference is made up for by the increased capability of the system over HVDC: the HIS offers a 0.357 \$/kWh lower LCOS, as well as having more flexibility in terms of storage use case.f This will likely offset the cost of added power electronics converters and storage which would need to be added to the HVDC system to enable the same functionality.

#### 6.2. Offshore Wind - North Atlantic Ocean

496

Deep sea wind farms have the potential to harness large quantities of renewable energy in locations further from shore, where wind energy is stronger and more reliable. Currently, offshore wind farms are located relatively close to shore in the UK, at distances less than 100

km [42]. However, new technology developments - specifically floating offshore wind - and increases in wind energy capacity will inevitably result in more large scale wind plants being built further offshore in the medium/long term. One location of interest for this purpose is in the North Atlantic Ocean in the west of Scotland, where there is over 60000km<sup>2</sup> of land available to harness wind energy [43]. Wind farms located up to 500km from the coast would likely suffer extreme cases of stranded electricity supply, and will also require large scale storage to increase security of supply to mainland electricity grids. Following this, the focus of this case study is the transport of offshore wind energy to areas of high demand via sub-sea hydrogen pipeline.

The case study considers a renewable energy source of a large scale, 4GW floating offshore wind farm 500km due west of Inverness in the North Atlantic Ocean. Energy is converted into hydrogen at the wind farm using PEM electrolysers, transported approximately 800km to the coast at Liverpool, UK, where it is reconverted back to electricity for utilisation. This system represents a high capacity, long distance use case for the HIS, using offshore wind energy prices for electricity price considerations. To reduce costs, a 50cm diameter pipeline is considered, with low frequency charging/discharging to account for intermittency of the farm: the pipeline is discharged to 75% of initial pressure, cycled every 2 days.

The results show that despite having a 0.087 \$/kWh higher LCOE, the HIS has a 2331 M\$ lower initial investment cost, due to the high capital cost of using 2x 1000MW HVDC subsea cables outweighing the cost of the electrolyser and H2GT. The hydrogen system also performs better than HVDC from a storage perspective, with a levelised cost 0.046 \$/kWh less than the equivalent HVDC system using salt cavern storage.

## 6.3. Solar Power - Morocco to UK Interconnector

The final case study considers a similar scenario to that of Case Study 6.2: a large capacity, long distance system. However, this system considers solar power as the input electricity source, using prices sourced from [44]. The system considers the delivery of 1.5GW of solar power from Morrocco to Southampton, UK. Such a system could be used to enable energy trading between the two countries, as well as diversifying the renewable

supply in the UK: Morocco has significantly greater access to solar energy, with a 2GW plant already in operation in Ouarzazate, and is expected to scale up solar electricity production significantly towards 2050 [45]. As a result, the importing of solar energy from Morocco would help reduce over reliance of the UK grid on wind energy, which may help ease the transition away from fossil fuels.

The results shown in Table 3 demonstrate the lower costs of the HIS at extremely long distances, with an initial investment cost 2635 M\$ less than the equivalent HVDC system.

In addition, the HIS has significant advantages from a storage perspective, with a LCOS 4x less than that of the HVDC system. This demonstrates the benefits of the HIS when used for large scale storage.

### 7. Conclusions

545

546

549

550

551

This paper presents the techno-economic analysis of a Hydrogen Interconnector System (HIS), using the Levelised Cost of Electricity/Storage (LCOE/LCOS) methods. The cost of electricity was determined for the base case of a 1000MW, 100km system under 'high', 'medium' and 'low' scenarios, based on construction years in 2020, 2025, 2030 and 2050. The system was compared with an equivalent High Voltage Direct Current (HVDC) system in all scenarios, and applied to 3 case studies.

The results show that the total cost of the HIS is highly sensitive to the cost of input electricity and efficiency of the hydrogen-electricity or electricity-hydrogen conversion. The compressor and pipeline both contribute less than 2% to the total capital costs of the system, resulting in minimal economic benefit to a compressorless system or short distance pipeline. The most cost effective HIS uses a gas turbine at pipeline outlet for construction in 2020-2030, being replaced by a fuel cell combined with a Direct Current to Alternating Current converter in 2050.

The system is competitive with HVDC (same amount of storage) from a LCOE perspective for all scenarios when considering construction in 2050, with lower costs at distances above 350km for a 1GW system. The system has a lower LCOS than an HVDC system using long duration hydrogen storage for construction from 2030, with the potential to be

competitive in 2025. The HIS outperforms the HVDC from storage perspectives for all case studies, with 15-20 % lower investment costs for 2 case studies analysed.
