## ABSTRACT

We present a *Herschel*/Spectral and Photometric Imaging Receiver (SPIRE) survey of three protoclusters at  $z = 2-3$  (2QZCluster, HS1700, SSA22). Based on the SPIRE colours ( $S_{350}/S_{250}$  and  $S_{500}/S_{350}$ ) of 250  $\mu\text{m}$  sources, we selected high-redshift dusty star-forming galaxies potentially associated with the protoclusters. In the 2QZCluster field, we found a  $4\sigma$  overdensity of six SPIRE sources around 4.5 arcmin ( $\sim 2.2$  Mpc) from a density peak of H $\alpha$  emitters at  $z = 2.2$ . In the HS1700 field, we found a  $5\sigma$  overdensity of eight SPIRE sources around 2.1 arcmin ( $\sim 1.0$  Mpc) from a density peak of Lyman-break galaxies at  $z = 2.3$ . We did not find any significant overdensities in SSA22 field, but we found three 500  $\mu\text{m}$  sources are concentrated 3 arcmin ( $\sim 1.4$  Mpc) east to the Ly $\alpha$  emitters overdensity. If all the SPIRE sources in these three overdensities are associated with protoclusters, the inferred star formation rate densities are  $10^3-10^4$  times higher than the average value at the same redshifts. This suggests that dusty star formation activity could be very strongly enhanced in  $z \sim 2-3$  protoclusters. Further observations are needed to confirm the redshifts of the SPIRE sources and to investigate what processes enhance the dusty star formation activity in  $z \sim 2-3$  protoclusters.

**Key words:** galaxies: formation – galaxies: high-redshift – infrared: galaxies – submillimetre: galaxies.

## 1 INTRODUCTION

The central regions of local clusters are dominated by passive early-type ellipticals and spheroidals, their stellar populations are old,

with inferred formation redshifts of  $z \gtrsim 2$  (e.g. Ellis et al. 1997). High-redshift dusty star-forming galaxies (DSFGs) are strongly star-forming galaxies [star formation rate (SFR)  $\gtrsim 100-1000 M_{\odot} \text{ yr}^{-1}$ ] and have been proposed to the precursors of present-day ellipticals in local clusters (e.g. Lilly et al. 1998; Smail et al. 1998; Lutz et al. 2001; Ivison et al. 2013). Large hydrodynamical simulations and galaxy formation models predict intense star formation could be

<sup>d</sup>The area where the integration time is greater than 30 per cent. For COSMOS field, we used centre of 3422 arcmin<sup>2</sup> area. We detected sources within this area (see also Fig. 3).

<sup>e</sup>The total integration time. For the survey design of COSMOS field, please see Oliver et al. (2012).

<sup>f,g</sup>The confusion noise and instrumental noise.

detectable as concentrations of DSFGs in  $z \gtrsim 2$  protoclusters (e.g. Granato et al. 2015). Indeed, there have been reports of a reversal of the SFR-density relation (e.g. Elbaz et al. 2007; Tran et al. 2010), which is increasing SFR with increasing local density at  $z \gtrsim 1$ . Protoclusters at  $z \gtrsim 2$  are thus unique laboratories to explore bursting star-formation in a critical epoch of galaxy formation (Casey 2016).

A number of studies have confirmed the presence of DSFGs in  $z < 2$  galaxy clusters (e.g. Brodwin et al. 2013; Smail et al. 2014; Ma et al. 2015; Webb et al. 2015), while studies confirming DSFGs at  $z \gtrsim 2$  protoclusters are also progressing (e.g. Tamura et al. 2009; Clements et al. 2014; Umehata et al. 2014, 2015; Casey et al. 2015). Some surveys to search for DSFGs at far-infrared (FIR) wavelengths have focused on radio galaxy fields (e.g. Stevens et al. 2003; Valtchanov et al. 2013; Dannerbauer et al. 2014; Rigby et al. 2014). Radio galaxies are thought to be tracers of large-scale structures, and some fraction of  $z \gtrsim 2$  protoclusters around radio galaxies indeed appear to have experienced bursting dusty star formation related to DSFGs (e.g. Ivison et al. 2000). However, such regions may be biased by the end to host a currently accreting supermassive black hole and so we also need to explore DSFGs large-scale structures selected by other techniques at  $z \gtrsim 2$  to investigate bursting star formation more generally. Clements et al. (2014) investigated  $\sim 90$  deg<sup>2</sup> sky observed as part of the *Herschel* Multi-tiered Extragalactic survey (HerMES) with *Planck* and *Herschel* to search for clusters undergoing dusty star formation. They found four candidate clusters, and for all four cases they found evidence of galaxy clusters with red sequence based on optical/NIR data. The SFR density of these at  $z \gtrsim 2$  are four order of magnitudes higher than the cosmic averaged values. But is this also true for dusty star formation in known optical/UV-selected galaxy clusters at  $z \gtrsim 2$ ?

In this paper, we report a result of observations with the Spectral and Photometric Imaging Receiver (SPIRE; Griffin et al. 2010) on the *Herschel Space Observatory* (Pilbratt et al. 2010) for three protoclusters at  $z = 2$ –3 (2QZCluster, HS1700, and SSA22 at  $z = 2.2, 2.3,$  and  $3.1,$  respectively). The three protoclusters have filamentary, large-scale structures of rest-frame UV to optical selected galaxies. The structure of this paper is as follows. In Section 2, we introduce the *Herschel*/SPIRE observations, the data processing, and our targeted fields. In Section 3, we present source detection methods, number counts, and SPIRE colour selection. In Sections 4 and 5, we present our results, discussion, and then summarize our main findings. We use the following cosmological parameters:  $\Omega_m = 0.3,$   $\Omega_\Lambda = 0.7,$   $h = 0.7$ . In this cosmology, the Universe is 2.9, 2.8, and 2.0 Gyr old and 1.0 arcsec corresponds

to 8.3, 8.2, and 7.6 kpc in physical length at  $z = 2.2, 2.3,$  and  $3.1,$  respectively.

## 2 OBSERVATIONS AND TARGET FIELDS

### 2.1 SPIRE observations

Our *Herschel*/SPIRE observations were performed as part of the second Open Time *Herschel* programmes (PI: Y. Matsuda). We summarize the observations in Table 1. The observations were executed in Large Map mode with a scan rate of 30 arcsec s<sup>-1</sup>, repeated 14 times for each field ( $N_{\text{rep}} = 14$ ). The dates of observations are 2012 June 22 (2QZCluster), 2012 March 4 (HS1700), and 2012 May 10 (SSA22). The coverage of the maps are  $\sim 23$  arcmin  $\times$  23 arcmin (2QZCluster),  $\sim 22$  arcmin  $\times$  22 arcmin (HS1700), and  $\sim 33$  arcmin  $\times$  33 arcmin (SSA22) corresponding to  $\sim 40$ – $60$  comoving Mpc at the protocluster redshifts, which are sufficient to search for concentration of DSFGs around the density peak of protocluster members. The integration times are 1.8, 1.5, and 3.7 h for 2QZCluster, HS1700, and SSA22, respectively. Maps were produced with the *Herschel* Interactive Processing Environment (HIPE, v11.0.0), following the standard data processing and map-making steps with destriping. The full width at half-maximum (FWHM) of the SPIRE beam is 18.1, 24.9, and 36.6 arcsec at 250, 350, and 500  $\mu\text{m}$ , respectively (Swinyard et al. 2010). The final maps have pixel sizes of 6, 10, and 14 arcsec at 250, 350, and 500  $\mu\text{m}$ . We measured the  $1\sigma$  confusion noise ( $\sigma_{\text{conf}}$ ) as map variance of flux density within effective area (Table 1), which are slightly higher than the values of blank fields (Nguyen et al. 2010). The instrumental noise measured in our three protoclusters is about one-third of the confusion noise (Table 1).

### 2.2 Protocluster targets

2QZCluster: this protocluster was originally identified as a concentration of five quasi-stellar objects (QSOs) in a  $\sim 1$  deg region at  $z = 2.23$  from the 2dF Quasar Redshift survey (Croom et al. 2001, 2004). Four out of the five QSOs are even more strongly clustered in a  $30 \times 30$  comoving Mpc patch. An H $\alpha$  narrow-band imaging revealed a filamentary large-scale structure of an overdensity of 22 H $\alpha$  emitters (HAEs) connecting the QSOs (Matsuda et al. 2011). *Chandra*/Advanced CCD Imaging Spectrometer (ACIS) 100 ks observations of this structure also showed evidence that the active galactic nucleus (AGN) fraction is a factor of  $\sim 3.5$  higher than blank fields (Lehmer et al. 2013).

**Table 2.** Summary of *Herschel*/SPIRE sources in the three protoclusters.

Field	Area <sup>a</sup> (arcmin <sup>-2</sup> )	N <sup>b</sup> (prior)	N <sup>c</sup> (catalogued)	N <sup>d</sup> (selected)	N <sup>e</sup>	Σ <sup>f</sup> (arcmin <sup>-2</sup> )	Σ <sup>g</sup> (arcmin <sup>-2</sup> )	δ <sup>h</sup>	σ <sup>i</sup>

HS1700: this protocluster was originally discovered as a  $\sim 7 \times$  density contrast redshift spike of UV/optical-selected star-forming galaxies (BX/BM) within a  $\sim 25$  comoving Mpc region at  $z = 2.30$  (Steidel et al. 2005). A Ly $\alpha$  narrow-band imaging survey revealed a filamentary large-scale structure of six giant Ly $\alpha$  Blobs (LABs; Erb, Bogosavljević & Steidel 2011). *Chandra*/ACIS-I 200 ks observations of this structure also showed tentative evidence of an enhancement of AGN fraction compared to the field environment (Digby-North et al. 2010).

SSA22: this protocluster was originally discovered as a  $\sim 4\text{--}6 \times$  density contrast in redshift distribution of Lyman-break galaxies (LBGs) and Ly $\alpha$  emitters (LAEs) within a  $\sim 20$  comoving Mpc region at  $z = 3.09$  (Steidel et al. 1998, 2000). A wide-field Ly $\alpha$  narrow-band imaging survey with Subaru Telescope revealed a filamentary large-scale structure of 283 LAEs, extended to at least  $\sim 60$  comoving Mpc (Hayashino et al. 2004). This sample of LAEs includes 35 LABs with sizes of 30–150 kpc scale (Steidel et al. 2000; Matsuda et al. 2004). *Chandra*/ACIS-I 400 ks observations of this structure showed that the AGN fraction of protocluster members is  $\sim 3 \times$  higher than that in the field environment (Lehmer et al. 2009a,b).

Blank field (COSMOS): we have chosen well-studied extragalactic field Cosmic Evolution Survey (COSMOS) to use as a blank field, which is observed as a part of HerMES (Oliver et al. 2012). The SPIRE map in COSMOS field is larger and deeper than our observations, so we have reprocessed them by limiting to the same depth using  $N_{\text{rep}} = 14$ . Subsequently, we apply the same map making, and source detection procedure in order to make sure that we match the

depth of our observations. The confusion and instrumental noise values are given in Table 1.

### 3 ANALYSIS

#### 3.1 DETECTION AND NUMBER COUNTS

The source detection was conducted on the 250 μm maps, because of the better spatial resolution compared with longer wavelength bands. We caution that 500 μm detection causes a source blending (even 250 μm can deblend these) and large spatial uncertainty. We used the SUSSEXTRACTOR (Smith et al. 2012) for the source detection and photometry. We detected S/N > 2 sources in the maps within the region where the integration time is greater than 30 per cent of the deepest parts (515 arcmin<sup>2</sup> for 2QZCluster, 497 arcmin<sup>2</sup> for HS1700, 1076 arcmin<sup>2</sup> for SSA22, and 3422 arcmin<sup>2</sup> for COSMOS field). We measured 350 and 500 μm fluxes at the positions of sources detected in the 250 μm maps, then listed these 250 μm sources only if the flux density is above 12 mJy in at least one of the SPIRE bands (See also Table 3–5, and the full tables are available online). This flux density limit corresponds to  $\sim 4\sigma$  of the instrumental noise and  $\sim 2\sigma$  of the confusion noise in all three bands. For SSA22, we cut out the region shown in Fig. 3 due to the high background fluxes from the Galactic cirrus.

We compared these SPIRE number counts with COSMOS field. We show the raw (i.e. not corrected for the completeness) number counts in Fig. 1 (See also Table 6–9). The raw number counts are roughly consistent with COSMOS field data at >20 mJy bin at 250

**Figure 1.** Number counts at 250, 350, and 500  $\mu\text{m}$  in the three protoclusters and COSMOS field. We detected  $S/N > 2$  sources in the 250  $\mu\text{m}$  maps and measured the 350 and 500  $\mu\text{m}$  fluxes at the positions of the 250  $\mu\text{m}$  sources. We fitted the data points of COSMOS field with a bézier curve. The number counts of the SPIRE sources in the protoclusters averaged over their full fields are roughly consistent with those of COSMOS field. The number counts of the SPIRE sources in COSMOS field are also consistent with those of HerMES blank fields (Béthermin et al. 2012), suggesting that COSMOS field can be used as a control field.

**Table 6.** Number of sources which have fluxes above 12 mJy in each bands.

	COSMOS	SSA22	HS1700	2QZCluster
250 $\mu\text{m}$	2552	699	356	365
350 $\mu\text{m}$	1944	529	259	260
500 $\mu\text{m}$	961	252	133	116

and 350  $\mu\text{m}$ . A moderate excess of number counts at  $S_{350} > 50$  mJy and  $S_{500} > 40$  mJy were found (by a factor of 2–3) in HS1700 and 2QZCluster, although they are within the error bars based on Poisson noise. We also compared number counts in COSMOS field with wider HerMES survey data (Béthermin et al. 2012). The number counts in COSMOS field agree with that of HerMES survey data, suggesting that COSMOS field is suitable as a control field.

**Table 7.** Number counts at 250  $\mu\text{m}$ . The errors take into account the statistical uncertainties, including the Poisson noise.

### 3.2 SPIRE colour selection

In order to search for DSFGs possibly associated with the protoclusters, we applied a colour constraint to the SPIRE-detected sources. The  $S_{350}/S_{250}$  and  $S_{500}/S_{350}$  colours were used to select the sources with single grey-body spectral energy distributions (SEDs) at the protocluster’s redshift ranges, with dust temperatures of  $T_d = 30$ – $40$  K, and a dust emissivity  $\beta = 1.5$ . Casey et al. (2012) measured the dust temperatures of SPIRE-selected DSFGs and showed that they are in the range of  $T_d = 20$ – $60$  K. The dust-emissivity index is determined by Hildebrand (1983), and typically  $\beta = 1.0$ – $2.0$  for DSFGs. Different values of  $\beta$  do not significantly affect our conclusion, yielding almost the same temperature and SPIRE colours. We included flux errors of  $\pm 20$  per cent in estimating the uncertainties in the SPIRE colours. Fig. 2 shows  $S_{500}/S_{350}$  versus  $S_{350}/S_{250}$  colour–colour diagram of the SPIRE sources in the three protoclusters.

We derived  $L_{\text{FIR}}$  (8–1000  $\mu\text{m}$ ) by fitting single grey-body SEDs with  $T_d$ , a free parameter. From the sources selected based on the SPIRE colours, we further applied an FIR luminosity cut of  $L_{\text{FIR}} \geq 5.0 \times 10^{12} L_{\odot}$  for conservative searching for DSFGs. Thus, the lowest flux densities in our samples are (36.0, 30.0, 19.4) mJy for 2QZCluster, (28.8, 26.3, 15.2) mJy for HS1700, and (15.6, 19.2, 12.9) mJy for SSA22 in the SPIRE bands (250, 350, 500)  $\mu\text{m}$ , respec-

tively. We finally obtained a sample of colour-selected bright SPIRE sources with colours consistent with the protocluster redshifts by rejecting  $\sim 95$  per cent of the 250  $\mu\text{m}$  sources (thus we select just 12/643 (2 per cent), 26/579 (5 per cent), and 55/1253 (4 per cent) colour-selected bright SPIRE sources in 2QZCluster, HS1700, and SSA22). For COSMOS field, we applied the same colour selection as the three protoclusters to obtain a control sample of field galaxies. We have selected 111/4923 (2 per cent), 140/4923 (3 per cent), and 262/4923 (5 per cent) colour-selected bright SPIRE sources in COSMOS field for 2QZCluster, HS1700, and SSA22 (see also Table 2).

## 4 RESULTS

### 4.1 Search for overdensities

We searched for overdensities in an aperture with a radius of 6 comoving Mpc (3.8, 3.7, and 3.2 arcmin radius for  $z = 2.2, 2.3,$  and  $3.1$ , respectively). This scale corresponds to physical scale of  $\sim 1.5$ – $2$  Mpc radius for each protocluster redshift, matching the size of the overdensity of DSFGs around radio galaxies (e.g. Dannerbauer et al. 2014; Rigby et al. 2014). We put down a grid of these apertures every 10 arcsec for the protoclusters and COSMOS field,

**Figure 2.**  $S_{500}/S_{350}$  versus  $S_{350}/S_{250}$  colour–colour diagram of the 250  $\mu\text{m}$  sources. From left to right, we show the plots for 2QZCluster, HS1700, and SSA22. We selected candidates of DSGFs possibly associated with the protoclusters whose colours are consistent with a single grey-body SEDs including a photometric error of  $\pm 20$  per cent (shaded regions). We assume the protocluster redshifts, dust temperatures of  $T_d = 30\text{--}40$  K and dust emissivity  $\beta = 1.5$ . The grey solid and dashed lines show tracks of single grey-body SEDs for different  $\beta$ . We plot sources with fluxes above 12 mJy in least one SPIRE bands as small grey points. The coloured larger/smaller symbols show sources with  $L_{\text{FIR}}$  larger/smaller than  $5.0 \times 10^{12} L_{\odot}$ . The error bars show the average errors of colour-selected bright SPIRE sources. We have selected 2 per cent, 5 per cent, and 4 per cent colour-selected bright SPIRE sources to search for overdensities of DSGFs in 2QZCluster, HS1700, and SSA22. We plot the expected colours for Arp 220 as a function of redshifts (Polletta et al. 2007) for comparison. We plot open circles on track of Arp 220 every  $z = 0.5$  from  $z = 0$  to  $z = 5.5$ .

and counted the number of colour-selected bright SPIRE sources ( $L_{\text{FIR}} \geq 5.0 \times 10^{12} L_{\odot}$ ) within each aperture. For SSA22, we excluded a high background region (see in Fig. 3).

We found  $3.9\sigma$  and  $5.0\sigma$  overdensities in the 2QZCluster and HS1700 fields, respectively, but did not find any significant ( $>3\sigma$ ) overdensities in the SSA22 field. We calculated the significance of overdensity,  $\sigma_{\text{pc}} = (n_{\text{pc}} - n_{\text{ave}})/\sigma_{\text{ave}}$ , where  $n_{\text{pc}}$  is the number of colour-selected bright SPIRE sources in overdense region (6 comoving Mpc search radius) of the protocluster fields,  $n_{\text{ave}}$  is the average number within a 6 comoving Mpc search radius for COSMOS field, and  $\sigma_{\text{ave}}$  is the standard deviation of  $n_{\text{ave}}$ . We also searched for overdensities of colour-selected bright SPIRE sources in case for 10 per cent and 30 per cent flux error boundaries in Fig. 2. The result does not significantly change for 20 per cent and 30 per cent boundaries. We found that 30 per cent boundary shows same position of overdensities of colour-selected bright SPIRE sources compared with that of 20 per cent boundary in 2QZCluster and HS1700. We found 10 per cent boundary is not suitable because the number of colour-selected bright SPIRE sources are too small to search for overdensities. In Fig. 3, we show the sky distribution of the colour-selected bright SPIRE sources. We also show the density of 19 HAEs and 3 QSOs (Matsuda et al. 2011) for 2QZCluster, 45 LBGs for HS1700 (Rudie et al. 2012; Steidel et al. 2014), and 742 LAEs for SSA22 (Yamada et al. 2012), respectively.

We searched for overdensities of the colour-selected bright SPIRE sources in the COSMOS field in an identical manner as for the protocluster fields. We plot the density distribution of the colour-selected bright SPIRE sources for the 2QZCluster, HS1700, and COSMOS fields in Fig. 4. The histogram shows the distribution of the number of colour-selected bright SPIRE sources within a 6 comoving Mpc aperture (normalized by the number of searched apertures). We found that 2QZCluster has a low number of sources. The fraction of the apertures which have no sources is about two times higher compared with COSMOS field. This suggests that there is a void like distribution while there are also overdensities in 2QZCluster. In contrast, HS1700 tends to have larger number of colour-selected bright SPIRE sources in the search apertures.

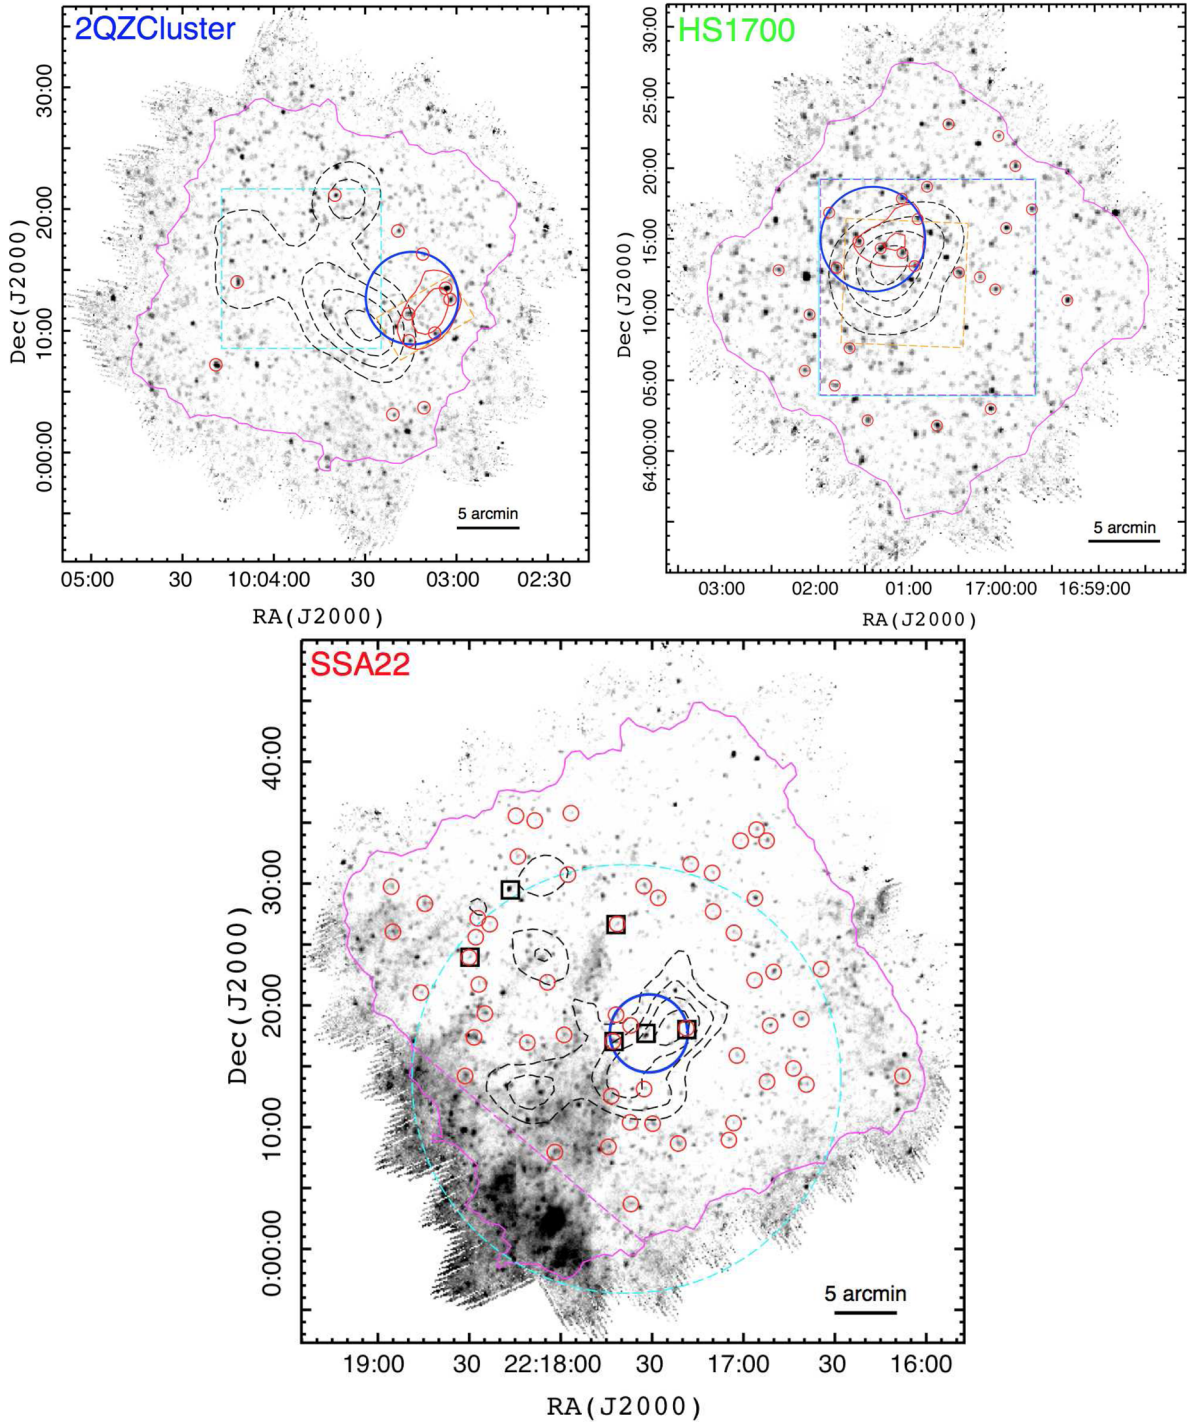

We also plot the cumulative number of the circles in Fig. 4. We normalized the cumulative number of COSMOS field to the protoclusters. We found that the normalized cumulative number with  $>3.9\sigma$  overdensities in 2QZCluster field is about two times higher than that in the COSMOS field. There are no overdensities in the COSMOS field which contain eight colour-selected bright SPIRE sources ( $5.0\sigma$ ) as HS1700. This means that such overdensities are preferentially located in the protoclusters.

## 4.2 2QZCLUSTER

In the 2QZCluster field, an overdensity of colour-selected bright SPIRE sources were found 4.5 arcmin ( $\sim 2.2$  Mpc) west to the HAEs overdensity.

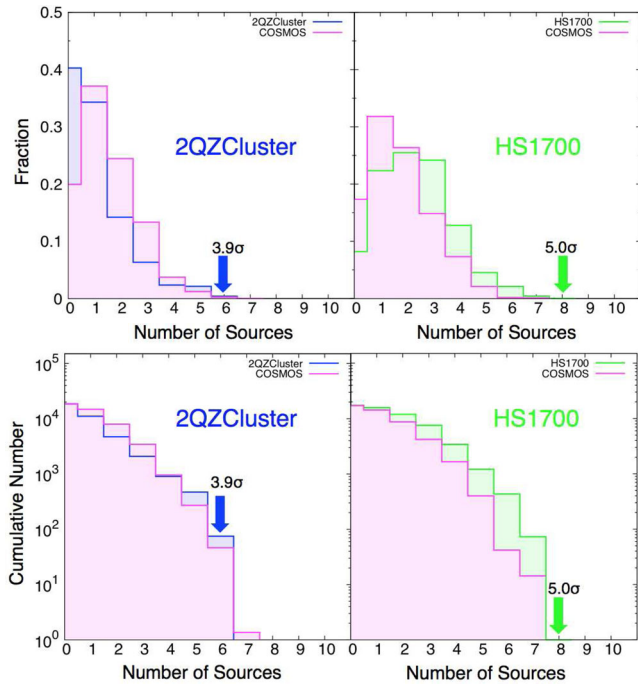

We searched for the counterparts of SPIRE sources with HAEs and QSOs in 2QZCluster, which are summarized by Matsuda et al. (2011), although the SPIRE overdense region did not have H $\alpha$  image with United Kingdom Infrared Telescope (UKIRT)/Wide Field Camera (WFCAM) (see Fig. 3). In total, 19 HAEs and 3 QSOs are within the 174 arcmin<sup>2</sup> overlap region. We define the following quality criteria based on Downes et al. (1986) for assessing the robustness of identified candidate counterparts. We classify sources with  $p \leq 0.05$  as secure counterparts, and those with  $0.05 < p \leq 0.10$  as tentative counterparts. We calculated the  $p$ -value defined by  $p = 1 - \exp(-\pi n \theta^2)$ , where  $n$  is the source density and  $\theta$  is the angular offset. We searched for counterparts within 11 arcsec radius from the centre of the SPIRE sources. This search radius corresponds to  $\sim 40$  per cent beam response in 250  $\mu\text{m}$  band.

For the QSOs, one optically luminous QSO, which is known as 2QZC-C1-HAE2 (Matsuda et al. 2011), coincides with one of our colour-selected bright SPIRE source 2QZCluster-SPIRE10 (2.7 arcsec offset). The  $p$ -value is lower than 0.01, suggesting a secure counterpart, the probability of chance association of counterparts is lower than 1 per cent. 2QZ-C1-HAE3 also coincides with our SPIRE source 2QZCluster-SPIRE124 (5.6 arcsec offset) as a secure counterpart. Such optically luminous FIR bright QSOs are thought to be in a transient phase between DSGFs and QSOs (Simpson et al.

**Figure 3.** Sky distributions of colour-selected bright  $250\ \mu\text{m}$  sources (red circles) overplotted on the SPIRE  $250\ \mu\text{m}$  maps. The areas outlined with magenta contour corresponds to the 30 per cent depth coverage. For SSA22, we do not use below the dashed magenta line due to the high background fluxes. The dashed black contours show the density of 19 HAEs and 3 QSOs (Matsuda et al. 2011) for the 2QZCluster, 45 LBGs for HS1700 (Rudie et al. 2012; Steidel et al. 2014), and 742 LAEs for SSA22 (Yamada et al. 2012), respectively. The steps show  $1\sigma$ – $4\sigma$ ,  $1\sigma$ – $5\sigma$ , and  $3\sigma$ – $6\sigma$  for 2QZCluster, HS1700, and SSA22 (smoothed with a Gaussian kernel with a FWHM of 6 comoving Mpc). The red contours show  $3\sigma$ – $4\sigma$ ,  $4\sigma$ – $5\sigma$  for colour-selected bright SPIRE sources in 2QZCluster and HS1700 with a same Gaussian kernel ( $1\sigma$  is standard deviation of surface density of colour-selected bright SPIRE sources measured in COSMOS field). The large blue circles show the overdensity of colour-selected bright  $250\ \mu\text{m}$  sources for 2QZCluster and HS1700, and colour-selected bright  $500\ \mu\text{m}$  sources for SSA22 using filtering a radius of 6 comoving Mpc. We find a  $4\sigma$  and  $5\sigma$  overdensity in the 2QZCluster and HS1700 fields. We do not find any significant overdensities of  $250\ \mu\text{m}$  sources in SSA22, but we found six colour-selected bright  $500\ \mu\text{m}$  sources (black squares), and three sources are concentrated 3 arcmin ( $\sim 1.4$  Mpc) east to the LAEs overdensity. The dashed cyan and orange boxes in 2QZCluster show the UKIRT/WFCAM (for HAEs) and Subaru/MOIRCS (for HAEs) coverage. The solid cyan, dashed purple, and orange boxes in HS1700 show the Keck/Low Resolution Imaging Spectrograph (LRIS) (for LAEs and LBGs, respectively) and Palomar/WIRC (for HAEs) coverage. The dashed cyan large circle in SSA22 shows Atacama Submillimeter Telescope Experiment (ASTE)/AzTEC coverage.

**Figure 4.** (Upper). The density distributions of the colour-selected bright SPIRE sources in 2QZCluster (left) and HS1700 (right) within an aperture radius of 6 comoving Mpc. 2QZCluster tends to have lower number of colour-selected bright SPIRE sources compared with COSMOS field. This could be explained if there are void-like structures within the survey area although there are also overdense regions. In contrast, HS1700 tends to have higher number of sources. (Lower). Cumulative number of the apertures with a radius of 6 comoving Mpc. We normalized the cumulative number of COSMOS field to the protoclusters.

2012). No other HAEs matched with colour-selected bright SPIRE sources. We then repeated this matching using all 250  $\mu\text{m}$  sources, and found five secure HAE counterparts (see Table 10).

We recently conducted Subaru/Multi-Object InfraRed Camera and Spectrograph (MOIRCS) follow-up NB imaging observations in 2015 May 5 to search for new HAEs as well as counterparts of the SPIRE sources in the SPIRE overdense region (4 arcmin  $\times$  7 arcmin; dashed orange box in Fig. 3). The total exposure time of  $K_s$  and NB data is each 1.5 and 2.4 ks, respectively. The  $5\sigma$  detection limit of NB  $< 19.8$  (Vega) is almost the same as the previous HAE search depth (NB  $< 19.9$  in Vega) by Matsuda et al. (2011).

We find no new HAE within the area. This may suggest that the area is actually a little underdense in terms of bright HAE, because Matsuda et al. (2011) claim an average field count of 0.09 per arcmin<sup>2</sup>, which corresponds to two or three HAEs per MOIRCS field of view (FOV). Such void structures adjacent to protocluster has been reported previously (e.g. Koyama et al. 2013; Saito et al. 2015).

### 4.3 HS1700

In HS1700, the overdensity peak of colour-selected bright SPIRE sources coincides with that of the protocluster member galaxies (2.1 arcmin offset, corresponding to  $\sim 1.0$  Mpc).

We searched for the counterparts of SPIRE sources using UV-selected (BX/BM) star-forming galaxies (LBGs), HAEs, LAEs, and Distant Red Galaxies (DRGs) in the SPIRE overdense region. There are 3010 LBGs within 256 arcmin<sup>2</sup>, 123 LAEs are within 219 arcmin<sup>2</sup>, 83 HAEs and 75 DRGs are within 72 arcmin<sup>2</sup>. The LBG catalogues are from the KBSS (Keck Baryonic Structure Survey; Rudie et al. 2012; Steidel et al. 2014). HS1700 is one of the 15 QSO fields intensively studied in KBSS. The  $H\alpha$  and  $Ly\alpha$  NB catalogues are from Milan Bogosavljević’s PhD thesis (Bogosavljević 2010). Individual properties of LBGs, LAEs and observations are described in Shapley et al. (2005), Erb et al. (2011), Kulas et al. (2013), and Erb et al. (2014). In addition, for the  $H\alpha$  narrow-band imaging, we used the Br  $\gamma$  filter (Palomar Wide Field Infrared Camera (WIRC), centre wavelength 2.17  $\mu\text{m}$ , FWHM = 297  $\text{\AA}$ ). The narrow band selection criteria are NB  $< 20.5$  (Vega) and NB  $-K_s \leq -0.75$ . The DRGs have selected with  $J - K > 2.3$  to a limit of  $K_s = 21$  (Vega). We define the quality criteria, and classify sources with  $p$ -value described above. We deduced the number density of 45 LBGs which have spectroscopically confirmed redshift in the protocluster (i.e. in the overdensity of  $z = 2.285\text{--}2.315$ ) separately from remaining 2965 LBGs outside of overdensity. We searched for counterparts within 11 arcsec radius from the centre of the SPIRE sources.

We found three colour-selected bright SPIRE sources that have secure counterparts (see Table 11). But one of the LAEs BNB1, the spectrum of this object is extremely odd and that makes difficult to identify the redshift. We identified it as a Lo-BAL QSO and it is more likely to have  $z \sim 2.00$ , so we do not treat as it is a protocluster member galaxy.

We also found that one LAE and LBG are secure, and one DRG and LAE are tentative counterparts of colour-selected faint (i.e.

<sup>a</sup>Redshift information of counterparts.

<sup>b</sup>Separation between SPIRE source and counterparts.

<sup>c</sup> $p$ -value based on Downes et al. (1986).

<sup>d</sup>We classify sources with  $p \leq 0.05$  as secure, and those with  $0.05 < p \leq 0.10$  as tentative counterparts.

<sup>e</sup>BNB1 is identified as a “Lo-BAL” QSO and therefore it is difficult to measure redshift.

<sup>f</sup>Photometric redshift from Chapman et al. (2015).

$L_{\text{FIR}} < 5.0 \times 10^{12} L_{\odot}$ ) SPIRE source. For the SPIRE sources which are not selected with our colour selection, but have at least one SPIRE band above 12 mJy, we found two secure LAEs, three secure HAEs, and one tentative HAE. Thus, we conclude that seven SPIRE sources in the overdensity have secure counterparts of protocluster galaxies (see Table 11).

In order to assess the success rate of the SPIRE colour selection, we compared the matching result for colour-selected bright/faint SPIRE sources and all 250  $\mu\text{m}$  sources lying within overdensity. We assumed that all HAEs and LAEs are associated with the protocluster except for BNB1, although we should note that the HAEs without spectroscopic follow-up are much less likely than spectroscopic confirmed HAEs to be at the cluster redshift. For all secure counterparts, the fractions are 2/7 (29 per cent), 1/5 (20 per cent), and 4/28 (14 per cent), respectively. This suggests that our SPIRE colour selection can select possible protocluster members with three times higher probability compared to not colour-selected sources.

In the HS1700 field, there are several foreground galaxy groups in the field. A  $z = 0.453$  group is very close to the position of HS1700-SPIRE24. Indeed, Peter et al. (2007) found that BX913 is lensed by the group. We calculated a magnification factor by using  $\text{GLAFIC}$  (Oguri 2010). We used a halo mass of  $M/h = 1 \times 10^{14} M_{\odot}$  (Israel et al. 2014) and a concentration parameter of  $c = 6$  (Bhattacharya et al. 2013). We found that the second nearest (1.5 arcmin away from group centre) SPIRE source is affected only  $\sim 5$  per cent magnification, so we conclude that only the HS1700-SPIRE24 could be affected by lensing.

#### 4.4 SSA22

The maximum number of colour-selected bright SPIRE sources found in 6 comoving Mpc aperture was five, corresponding to a  $1.6\sigma$  overdensity. This suggests that SSA22 does not have any significant overdensities of colour-selected bright 250  $\mu\text{m}$  sources. But, this could be a problem for SSA22 at  $z = 3.1$  because DSFGs would start to drop out at 250  $\mu\text{m}$ . Here, we searched for an overdensity of colour-selected bright 500  $\mu\text{m}$  detected sources with identical colour selection and luminosity cut in Section 3.2. We found six colour-selected bright 500  $\mu\text{m}$  sources in the SSA22 field, and three sources are concentrated 3 arcmin ( $\sim 1.4$  Mpc) east to the LAEs overdensity (Fig. 3). For 350  $\mu\text{m}$  sources, we did not find any significant overdensities as same as 250  $\mu\text{m}$  sources.

We investigated AzTEC 1.1 mm counterparts in Umehata et al. (2014, 2015) for the five colour-selected bright 500  $\mu\text{m}$  sources within  $\sim 800$  arcmin<sup>2</sup> overlapped region (Fig. 3). We searched for the counterparts within a radius of 14 arcsec (half of AzTEC 1.1 mm FWHM). We found that four colour-selected bright 500  $\mu\text{m}$  sources have been matched (SSA22-AzTEC1, 2, 5, and 34). Thus  $\sim 80$  per cent colour-selected bright 500  $\mu\text{m}$  sources are matched with AzTEC 1.1 mm sources.

## 5 DISCUSSION AND SUMMARY

We searched for DSFGs associated with three protoclusters at  $z = 2-3$  (2QZCluster, HS1700, SSA22) using *Herschel*/SPIRE. In the 2QZCluster and HS1700 field, we found  $4\sigma$  and  $5\sigma$  overdensities of the colour-selected bright SPIRE sources on a scale of 6 comoving Mpc. In the SSA22, we did not find any significant overdensities of 250  $\mu\text{m}$  sources, but we found that three colour-selected bright 500  $\mu\text{m}$  sources are concentrated on a scale of 6 comoving Mpc. The results suggest possible activity associated with enhanced dusty star formation in protoclusters at  $z \sim 2-3$ .

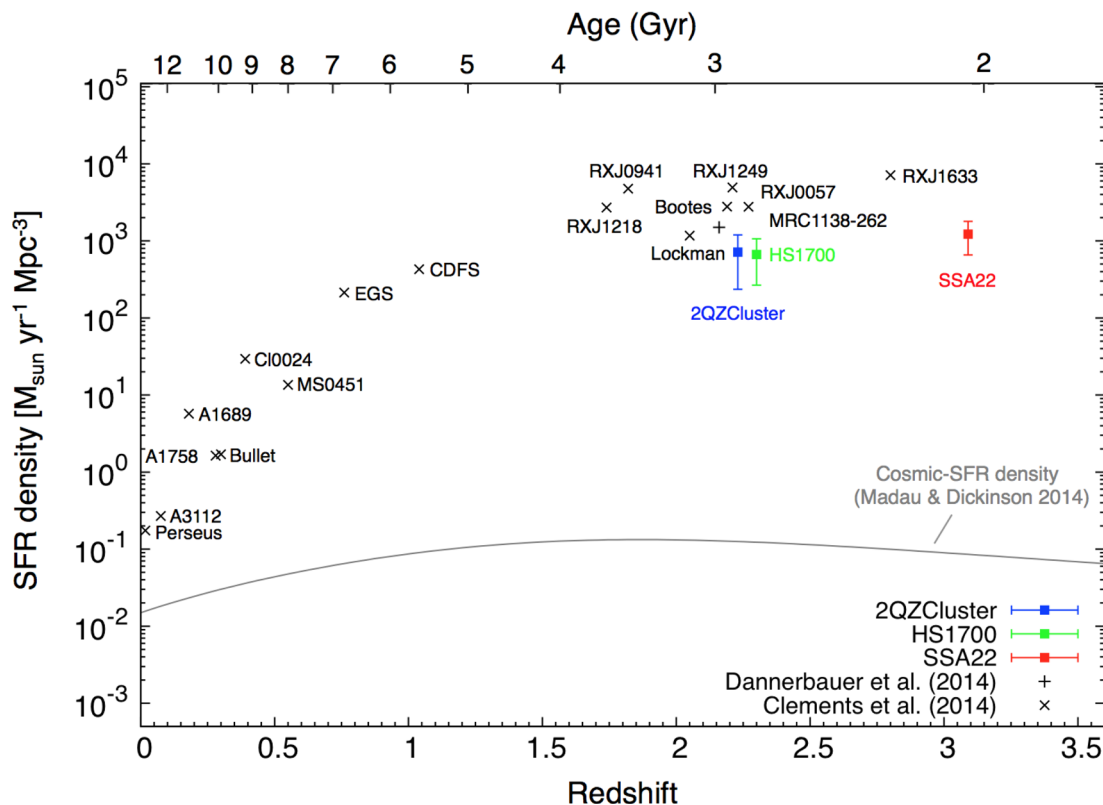

We derive the SFR density of 2QZCluster, HS1700, and SSA22 to compare with the average value of the Universe. The SFR of DSFGs is often converted from FIR luminosity, although the conversion from  $L_{\text{FIR}}$  to SFR is not straightforward and relies on the dust composition and initial mass function (IMF). Most works on DSFGs assume the conversion given by  $\text{SFR} (M_{\odot} \text{ yr}^{-1}) = 4.5 \times 10^{-44} L_{\text{FIR}} (\text{erg s}^{-1})$  or  $1.7 \times 10^{-10} L_{\text{FIR}} (L_{\odot})$  (Kennicutt 1998), where  $L_{\text{FIR}}$  is the integrated luminosity of 8–1000  $\mu\text{m}$ . This conversion takes the radiative transfer models of Leitherer & Heckman (1995) and a Salpeter IMF (Salpeter 1955).

We used a simple estimation to calculate the integrated SFR densities by assuming that all colour-selected bright SPIRE sources in the overdensities are associated with protoclusters. In addition, we also included sources with  $S/N > 2$  in all three SPIRE bands within a radius of 1 Mpc (physical) following Clements et al. (2014) analysis of *Planck* clumps with *Herschel*/SPIRE. Because this radius of 1 Mpc circles is smaller than our search radius (6 comoving Mpc,  $\sim 1.5-2$  Mpc in physical), we adjusted the position of the smaller aperture to contain as many colour-selected bright SPIRE sources as possible. This enables us to select regions similar to *Planck* clumps in Clements et al. (2014). The  $1\sigma$  instrumental noise of Clements's work ranges from 2.5 to 2.8 mJy at 250  $\mu\text{m}$ , 2.1 to 2.3 mJy at 350  $\mu\text{m}$ , and 3.0 to 3.3 mJy at 500  $\mu\text{m}$  (Clements et al. 2014), which is similar to our survey. For all SPIRE sources within a 1 Mpc radius, we fitted single grey-body SEDs with fixed  $T_d = 35$  K,  $\beta = 1.5$  and the protocluster's redshifts, and derived  $L_{\text{FIR}}$ . We excluded one colour-selected bright SPIRE source HS1700-SPIRE30 from this discussion because it is very close to  $z = 0.08$  Sloan Digital Sky Survey (SDSS) galaxy, and its *Spitzer*/Multiband Imaging Photometer for *Spitzer* (MIPS) 24  $\mu\text{m}$  flux density is very high ( $\sim 200$   $\mu\text{Jy}$ ). We found that MIPS 24  $\mu\text{m}$  flux densities of other colour-selected bright SPIRE sources in HS1700 are consistent with that of typical high- $z$  star-forming galaxies. 2QZCluster does not have any *Spitzer* images.

Fig. 5 shows our results and compare to previous studies in the literature. We calculated SFR with Bell (2003)'s  $L_{\text{FIR}}$  correction to follow Clements et al. (2014) analysis. The derived SFR densities are  $10^3-10^4$  times higher than the global SFR density seen in Madau & Dickinson (2014). This comparison indicates enhanced star formation activities in protoclusters at  $z \sim 2-3$ . The enhancement of dusty star-formation activity within our protoclusters is consistent with that seen for *Planck* clumps (Clements et al. 2014). Dannerbauer et al. (2014) presents results based on Atacama Pathfinder Experiment telescope (APEX)/Large Apex BOlometer CAmera (LABOCA) 870  $\mu\text{m}$  observations around MRC1138–262 at  $z = 2.16$ , showing that at least six DSFGs are likely part of the protocluster. The SFR density  $\sim 1500 M_{\odot} \text{ yr}^{-1} \text{ Mpc}^{-3}$  is similar to Clements et al. (2014) and our protoclusters study. We also plot the error bars in Fig. 5. The high end shows the case when including all sources in 1 Mpc radius and the low end shows the case for subtracting field average values. We deduced field values by calculating average number of sources and average luminosity in 1 Mpc radius apertures in the COSMOS field.

In Table 12, we summarized the estimated SFR and assumed volume plotted in Fig. 5. We also calculated SFR density in an aperture using a radius of 6 comoving Mpc in the same manner. These radii are 1.9, 1.8, and 1.5 Mpc in physical units for 2QZCluster, HS1700, and SSA22, respectively, and the results do not change compared to the case of 1 Mpc.

What causes the enhanced dusty star-forming activity in our protoclusters? One possible answer to this is galaxies mergers. For instance, Casey et al. (2015) investigated the morphology of the

**Figure 5.** SFR density of clusters, protoclusters, and global cosmic SFR densities. The SFR densities of our protoclusters are  $10^3$ – $10^4$  times higher than the global SFR density (Madau & Dickinson 2014). We show the compilation from Dannerbauer et al. (2014) and data from Clements et al. (2014), which original literature are following; *IRAS* measurements of Perseus from Meusinger, Brunzendorf & Krieg (2000), Balloon-borne Large Aperture Submillimeter Telescope (BLAST) measurements of A3112 from Braglia et al. (2011), *ISO* measurements of A1689 from Fadda et al. (2000), and *Spitzer* measurements of A1758 from Haines et al. (2009), Bullet cluster from Chung et al. (2010), CI0024+16 and MS0451-03 from Geach et al. (2006). RXJ0057, RXJ0941, RXJ1218, RXJ1249, and RXJ1633 are based on James Clerk Maxwell Telescope/Submillimetre Common-User Bolometer Array from Stevens et al. (2010).

galaxies in a protocluster to search for interaction/merger state by using *Hubble Space Telescope H*-band imaging data. Although the sample size is limited, they found that the fraction of irregular and interacting galaxies among the LBGs and DSFGs is 1.5 times higher in the protocluster than in the field. Webb et al. (2015) suggested that dusty star formation at the centre of a  $z = 1.7$  cluster is being driven by galaxy–galaxy interaction, involving a FIR luminous bright cluster galaxy. Because there are strong correlation between the major-merger and the FIR luminosity (Engel et al. 2010; Kartaltepe et al. 2010, 2012; Hung et al. 2013), higher major mergers rate in protoclusters could induce dusty star forma-

tion. *N*-body simulation also predicts that progenitors of cluster and group haloes at  $z > 2$  have 3–5  $\times$  higher major merger rates than isolated haloes (Gottlöber, Klypin & Kravtsov 2001). The fact that the colour-selected bright SPIRE sources are significantly concentrated in HS1700 and 2QZCluster would support such simultaneously major merging phenomenon. However, further observations are needed to investigate the processes of dusty star-forming activity in these protoclusters.

## ACKNOWLEDGEMENTS

We thank the anonymous referee for helpful comments which significantly improved the clarity of this paper. We thank Scott Chapman, James Colbert, Emanuele Daddi, Koichiro Nakanishi, and Kazuhiro Shimasaku for useful discussions and supports. Rhythm Shimakawa and Mariko Kubo made enormous contribution to analyses. We acknowledge Masaru Kajisawa for our use of his MOIRCS fringe-removal software (Kajisawa et al. 2015) during the data reduction.

*Herschel* is an ESA space observatory with science instruments provided by European-led Principal Investigator consortia and with important participation from NASA. SPIRE has been developed by a consortium of institutes led by Cardiff University (UK). Subaru Telescope, which is operated by the National Astronomical Observatory of Japan. UKIRT is funded by the STFC (UK). The W.M. Keck Observatory was made possible by the generous financial support of the W.M. Keck Foundation. The authors wish to recognize and acknowledge the very significant cultural role and

reverence that the summit of Mauna Kea has always had within the indigenous Hawaiian community. We are most fortunate to have the opportunity to conduct observations from this mountain.

This research was supported in part by a grant from the Hayakawa Satio Fund awarded by the Astronomical Society of Japan. YM acknowledges support from JSPS KAKENHI Grant Number 20647268. IRS acknowledges support from STFC (ST/L00075X/1), the ERC Advanced Grant DUSTYGAL (321334), and a Royal Society/Wolfson Merit Award. BH acknowledges support from JSPS KAKENHI Grant Number 15K17616. HU acknowledges support from Grant-in-Aid for JSPS Fellows, 26.11481.
