[1] Pseudotachylytes are accepted as recording paleo-seismicity in the rock record. However, the interpretation of the mechanics of faulting based on pseudotachylyte generation is often hindered because the depth at which they form is poorly constrained. Here, we use thermochronology to determine the depth at which pseudotachylytes in the Sierra Nevada, California, formed. The pseudotachylytes formed in  $\leq 10$  m long patches over a rupture surface, the rest of which comprised cataclasites that did not melt. The age of the pseudotachylytes is found to be  $76.6 \pm 0.3$  Ma ( $2\sigma$ ) from  $^{40}\text{Ar}/^{39}\text{Ar}$  dating of pristine vein matrix. A suite of thermochronometers define the temperature-time path of the host rock granodiorite from  $\sim 550$  to  $60^\circ\text{C}$ . When the pseudotachylytes formed, the ambient temperature was 110 to  $160^\circ\text{C}$ , implying a depth of  $\sim 2.4$  to 6.0 km under typical geothermal gradients. At these depths, the failure stress on optimally oriented faults with Byerlee friction and hydrostatic pore pressure was  $\leq 51$  MPa. Following melting, the dynamic stress acting on the fault is the melt shear resistance, which we calculate to be  $< 0.2$  MPa, suggesting that the stress drop associated with melting was complete. To conform with seismologically observed dynamic stress drops averaged over an entire rupture (1 to 10 MPa), dynamic stress drop must have varied by at least an order of magnitude between the parts of the fault that melted and those that did not. Constraining the depth of pseudotachylyte formation using thermochronology therefore provides a quantitative estimate of the degree and scale of coseismic stress heterogeneity.

## 1. Introduction

[2] Tectonic pseudotachylytes are the chilled remnants of frictionally induced melts found along fault surfaces [Philpotts, 1964]. The temperature rise required for melting implies that seismic slip rates (of the order of 0.1 to 1 m/s) are necessary for pseudotachylytes to form during a slip

event [Sibson, 1975]. Currently, pseudotachylytes are the only recognized indicator of ancient seismic activity in exposures containing exhumed faults [Cowan, 1999] and as such, they provide a unique tool for investigating seismic processes from the rock record.

[3] The presence of pseudotachylyte can place constraints on the stress state on the fault during rupture because for a given amount of slip, frictional heating is dependent on the shear stress if all of the mechanical work during slip is converted to heat [Sibson, 2003]. Some studies use the required temperature rise to estimate the average dynamic shear stress acting on the fault over the duration of slip [Sibson, 1975; Barker, 2005; Di Toro *et al.*, 2005; Andersen *et al.*, 2008]. However, interpreting the derived stress in terms of laboratory constraints on friction requires additional knowledge about the normal stress on the faults. Any further connection between the stress and the micromechanics of resistance rests on inferences about the depth of the pseudotachylyte formation [e.g., Fialko and Khazan, 2005], as the lithostatic stress places a minimum bound on the normal stress.

[4] Despite its importance, the depth of pseudotachylyte formation is often difficult to directly determine, particularly

**Figure 1.** Location and geology of the Kings Canyon national park study area. (a) Map of western North America showing the location of the study area (black circle). (b) Map showing the distribution of faults. Black lines are the Glacier Lakes system (GLF), dark gray lines the Granite Pass fault (GPF) system [after Kirkpatrick et al., 2008]. Unit abbreviations are as follows: Kpy = Pyramid pluton, Kpym = Pyramid pluton mafic western facies, Kk = Granite of Kennedy Lakes, Kjm = mafic plutonic rock, Kt = Granite of Tehipite Dome, Kwd = Granodiorite of White Divide, Knd = Granodiorite of North Dome, ch = calc-hornfels, Mzr = metarhyolite tuff, Kp = Paradise pluton, Ka = Arrow pluton, Kmb = Granodiorite of Muro Blanco, Kdp = Granite of Dougherty Peak [from Moore, 1978]. Open square is the location sampled for  $^{40}\text{Ar}/^{39}\text{Ar}$  analysis, open circle shows the location of host rock samples for the t-T analyses.

as pseudotachylytes are most often found in crystalline rocks [Sibson and Toy, 2006]. In contrast to pelitic rocks that form distinct equilibrium mineral assemblages over small variations in pressure and temperature [e.g., Yardley, 1989], felsic igneous rocks are less prone to react and therefore record less information about temperature and pressure conditions. At high pressures and temperatures some mineral assemblages within the pseudotachylytes or accompanying fault rocks can be used to estimate the depth at which pseudotachylytes were formed. For example, pseudotachylytes containing eclogite facies assemblages formed at depths in excess of 60 km [e.g., Austrheim and Boundy, 1994]. However, lower grade assemblages are less useful at pinpointing the depth of faulting within the upper 15 km of the seismogenic crust where the majority of earthquakes are observed to nucleate [Sibson, 1982]. Geochronological data can also be used to estimate depth if the exhumation rate since pseudotachylyte formation is constrained from independent evidence, allowing the depth to be found by dating the pseudotachylyte [Warr et al., 2007].

[5] In this study we use geochronological and thermochronological techniques to determine the depth at which pseudotachylytes in Kings Canyon national park, California were generated. The time at which the pseudotachylytes formed is found by precise  $^{40}\text{Ar}/^{39}\text{Ar}$  dating of the pseudotachylyte matrix. A suite of low temperature thermochronometers are used to constrain the time-temperature history of the host rock granodiorite. Integrating the two data sets provides a quantitative assessment of the ambient temperature when the pseudotachylytes formed, and the corresponding depth assuming a typical geothermal gradient.

[6] As an example of the utility of these depth constraints, we pursue the implications for coseismic stress variability on the fault. Stress is commonly recognized to be highly variable on a fault. However, the amplitude and scale of variations requires observational constraints. Field observations show that the lengths of fault-parallel pseudotachylyte veins are limited to 1 to 10 m along strike. Coseismic slip consistent with the lengths of the generation surfaces would not dissipate sufficient energy as heat to melt the rock, so the patches must have formed as part of larger ruptures [Kirkpatrick and Shipton, 2009]. We use the depth constraint to estimate the stress at the initiation of slip and the subsequent stress changes associated with melt formation during the paleo-earthquake that formed the pseudotachylytes. Stress drop in the pseudotachylyte-bearing parts of the faults is found by estimating the shear resistance of the melt layers. This stress drop must represent the dynamic stress drop, and we show that the constraints on the magnitude of the stress change may also apply to the static stress drop. Comparison with seismologically observed macroscopic static stress drops quantitatively constrains the variation in stress drop between the pseudotachylyte and non-pseudotachylyte parts of the fault.

## 2. Field and Microscope Observations of Pseudotachylyte-Bearing Faults

[7] Pseudotachylyte-bearing faults in Kings Canyon national park, California, USA [Kirkpatrick et al., 2008, 2009], cut the Cretaceous Pyramid pluton granodiorite [Moore, 1978] (Figure 1) with mapped trace lengths of  $\sim 1$  to 8 km, and total apparent left-lateral strike-slip

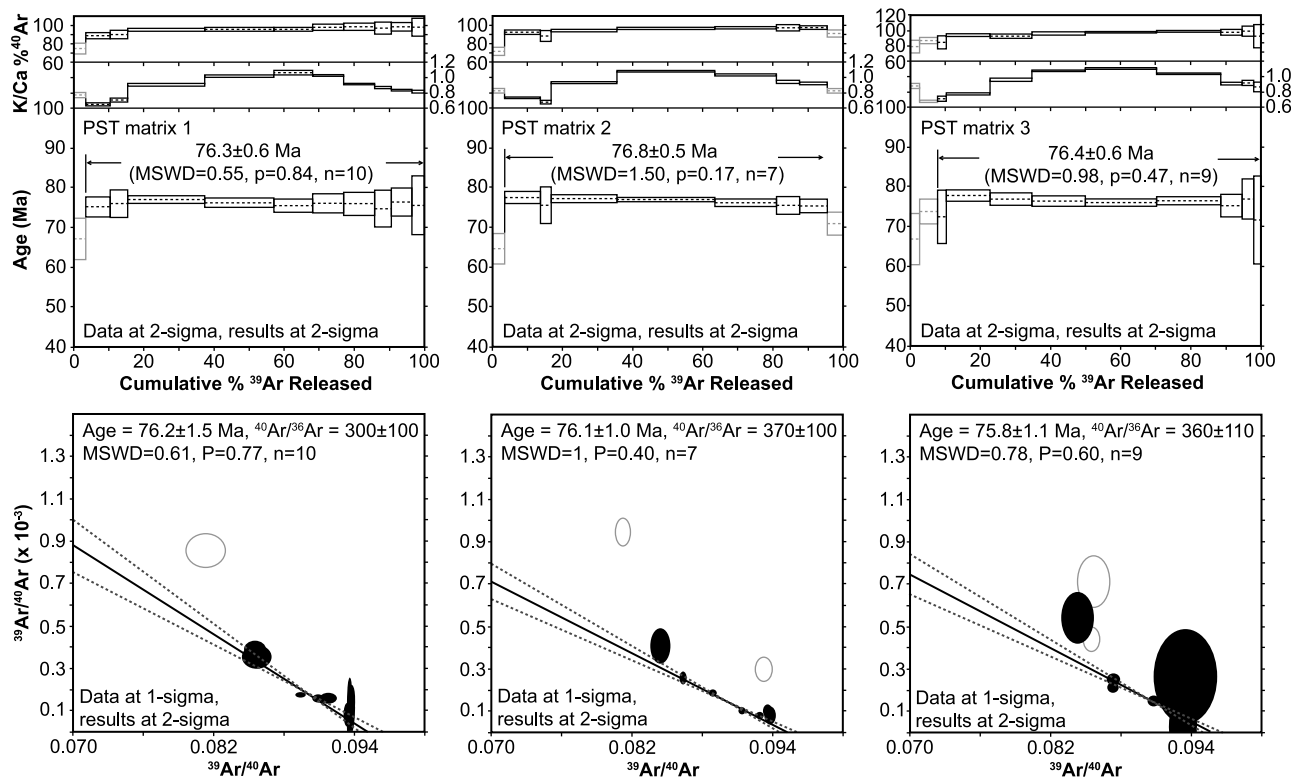

**Figure 2.** Pseudotachylytes in Kings Canyon national park. (a) Photograph of a narrow pseudotachylyte patch in the SKF. The fault-parallel vein (at the tips of the arrows) is banded and injection veins branch from the main fault vein at high angles. Hand lens for scale is 2.5 cm long. (b) Thin section photomicrograph (PPL, scale bar 1 mm) of the sample dated with  $^{40}\text{Ar}/^{39}\text{Ar}$ . Inset shows the hand specimen prior to vein separation (scale bar 1 mm). The pseudotachylyte contains rounded quartz and feldspar clasts dispersed in an isotropic matrix. (c) Scanning electron microscope backscattered electron (BSE) image of the same sample as in Figure 2b showing the typical texture of the pseudotachylyte. Clasts of quartz (Qtz), Ca-rich plagioclase (Pfsp), orthoclase (Kfsp), titanite and Fe-oxides (FeO) are indicated. The matrix is made up of lath-shaped microcrystallites of plagioclase, indicative of quench textures that form as the melt rapidly cools. (d) Detail of the matrix of the pseudotachylyte showing the pristine nature of the samples. At the finest scale of observation, the material consists of interlocking microcrystallites of plagioclase and even finer microcrystallites that likely have a biotitic composition (arrow, no label), though this is difficult to verify with EDS spectra because they are finer than the spot size of the beam. Abbreviations the same as in Figure 2c.

offsets up to  $\sim 80$  m. Slickenline orientations are predominantly sub-horizontal on each of the faults. Detailed fault rock descriptions and maps of fault rock distributions have previously been reported [Kirkpatrick *et al.*, 2008, 2009; Kirkpatrick and Shipton, 2009]. We summarize here the key meso- and micro-structural characteristics of the pseudotachylytes significant to the present study.

[8] The Kings Canyon faults consist of multiple cataclastic fault cores within which fault-parallel pseudotachylyte veins form thin patches that are discontinuous along strike. The fault-parallel patches represent generation surfaces across which opposing sides of the fault moved relative to one another at seismic slip rates, resulting in melting [Sibson, 1975]. Centimeter-scale injection veins branch from the fault-parallel veins at high angles and contain the same aphanitic, gray to black, cohesive material with

occasional rounded clasts of quartz and feldspar as the generation surfaces. Individual pseudotachylyte patches along the fault can be traced for  $\sim 5$  to 10 m along strike. Where they terminate, the pseudotachylytes trend into cataclasites in which there is no evidence for melting [Kirkpatrick and Shipton, 2009]. The cataclasites along strike from the pseudotachylyte patches are made up of fragments of host rock quartz, feldspars, hornblende and biotite and clasts containing previously formed cataclasites. Epidote and chlorite are abundant in the matrix of the cataclasites. Fault cores and fractures containing chlorite and epidote are surrounded by alteration haloes containing sericitized feldspars and chloritized biotites and hornblende.

[9] Multiple pseudotachylyte patches are observed on three individual faults, and qualitative field observations suggest less than 20% of the total fault lengths contain

**Figure 3.**  $^{40}\text{Ar}/^{39}\text{Ar}$  step heating spectra and isotope correlation plots for 3 aliquots of pseudotachylyte matrix. Gray points were rejected. Plateau calculations are based on the acceptance criteria of  $n = 3$  for the minimum number of contiguous steps with no resolvable slope,  $F = 0.60$  (that is,  $\geq 60\%$  of  $^{39}\text{Ar}$  released) and  $P = 0.05$  for the probability of fit. All inverse isochron ages for all 3 aliquots overlap with the associated plateau and integrated ages showing the  $^{40}\text{Ar}/^{39}\text{Ar}$  data to be robust. The  $^{40}\text{Ar}/^{36}\text{Ar}$  trapped components all overlap with accepted atmospheric values [Nier, 1950].

pseudotachylyte [Kirkpatrick *et al.*, 2009]. The fault-parallel pseudotachylyte patches are typically straight and  $\leq 10$  mm thick, although they locally reach  $\sim 20$  mm at geometrical irregularities such as jogs and steps. The pseudotachylytes are altered and replaced with epidote and chlorite with varying degrees. In pristine samples, the pseudotachylyte matrix contains microcrystallites that are tens to hundreds of  $\mu\text{m}$  long (Figure 2), indicative of quench textures [e.g., Philpotts, 1964] (see also the review by Magloughlin and Spray [1992]). Interlocking microcrystallites as small as  $10 \mu\text{m}$  long and  $1 \mu\text{m}$  wide make up the matrix in between the larger microcrystallites (Figure 2). Survivor clasts consisting of fragments of host rock minerals or previously formed cataclases are typically rounded and range in size from  $\sim 10 \mu\text{m}$  to several mm. Vesicles are not observed in any of the pseudotachylyte samples from the study area.

[10] We focus on pristine pseudotachylytes in the Skeeter fault (SKF), which displays the patchy geometry. In this fault, the pseudotachylytes crosscut all other cataclastic deformation textures in exposure and in thin section, indicating that they formed during the last slip event on the fault. Coseismic slip for ruptures with lengths equal to the patch dimensions (0.1 to 1 mm, assuming static stress drop of 1 to 10 MPa) is insufficient to raise the temperature of the slip zone and overcome the latent heat of fusion to initiate melting even for extremely narrow slip zones [Griffith *et al.*, 2008]. The discontinuous pseudotachylyte patches on the

SKF (as well as the other faults in the area) must therefore have formed in isolated patches over a rupture surface that was large compared to the 5 to 10 m long pseudotachylyte veins [Kirkpatrick and Shipton, 2009]. Empirical scaling relationships suggest that the largest earthquakes that could have occurred on the 1.4 km long SKF would have been  $\sim M4$  if the entire fault had ruptured [Wells and Coppersmith, 1994]. Other pseudotachylyte-bearing faults in the study area, such as the Granite Pass fault [Kirkpatrick *et al.*, 2008], are up to  $\sim 8$  km long and could have experienced a  $M5.8$  earthquake.

### 3. Age of Pseudotachylyte Generation From $^{40}\text{Ar}/^{39}\text{Ar}$ Analyses

[11] The timing of pseudotachylyte generation was determined by high-precision  $^{40}\text{Ar}/^{39}\text{Ar}$  dating of the pseudotachylyte matrix of a sample from the SKF. The heterogeneous nature of pseudotachylyte (Figure 2) makes bulk analyses challenging, and has led many recent studies to date pseudotachylyte by *in situ*  $^{40}\text{Ar}/^{39}\text{Ar}$  dating techniques [e.g., Sherlock *et al.*, 2008]. Although this allows linkage between petrographical observation and radioisotopic ages, it typically yields low-precision ages. To facilitate the determination of high-precision ages, we used a similar approach to Warr *et al.* [2007] and treated the pseudotachylyte samples as a phenocryst-rich basalt and

**Figure 4.**  $^{40}\text{Ar}/^{39}\text{Ar}$  step heating spectra and isotope correlation plots for (a, b) biotite and (c, d) hornblende.

step-heated three 6 mg aliquots of pure pseudotachylyte matrix.

[12] Pseudotachylyte veins were separated from the host rock with a slow rotation diamond saw. The vein material was crushed and sieved (63–125  $\mu\text{m}$ ). After magnetic separation and leaching in  $\text{HNO}_3$  and  $\text{HF}$ , clast-free fragments of melt were handpicked under a binocular microscope to reduce the chance of including survivor clasts of wall rock or pre-existing fault rocks. The aliquots were loaded into Cu packets and irradiated in the McMaster reactor with international standards Fish Canyon Tuff sanidine (FCs,  $28.201 \pm 0.023$  Ma [Kuiper *et al.*, 2008], used for J-parameter measurements,  $n = 60$ ), GA1550 biotite ( $98.8 \pm 0.5$  Ma [Renne *et al.*, 1998]) and Taylor Creek Rhyolite sanidine (TCR-2s,  $28.34 \pm 0.16$  Ma [Renne *et al.*, 1998]). The ages for GA1550 and TCR-2s were determined relative to FCs and overlap with accepted values showing J-parameter measurements to be appropriate.

[13] Aliquots were step-heated using a 25-W Merchanteck  $\text{CO}_2$  laser. Samples were heated for 20 s prior to 4.5 min cleanup. Extracted gases were cleaned using 2 GP50 SAES getters (450°C and room temperature) and a slush trap maintained at  $-140^\circ\text{F}$  using  $\text{CO}_2(\text{S})$  and acetone. Data were collected using an ARGUS multicollector mass spectrometer [Mark *et al.*, 2009], and the BGC software package Mass-Spec was used for data regression and age calculations. Isotope data are corrected for blank, radioactive decay, mass discrimination and interfering reactions.  $^{40}\text{Ar}/^{39}\text{Ar}$  ages also include error assigned to the J-parameter from the analysis of 30 monitors per sample. The atmospheric ratios of Nier [1950] were used to correct for mass discrimination and the decay constants of Steiger and Jäger [1977] were used for age calculations.

[14] All three aliquots of pseudotachylyte yielded concordant plateaux and the isotope correlation plots yielded inverse isochrons that overlap with the accepted atmospheric  $^{40}\text{Ar}/^{36}\text{Ar}$  value [Nier, 1950] and show no evidence of excess  $^{40}\text{Ar}$  (Figure 3, raw data are included in the auxiliary material).<sup>1</sup> Data points excluded from the plateau calculations were excluded from inverse isochron calculations. The reproducibility of the same age 3 times with different aliquots is striking in comparison to previous attempts to date pseudotachylyte by similar methods [e.g., Di Vincenzo *et al.*, 2004; Pennacchioni *et al.*, 2006] and suggests that contamination by the host rock is negligible because it is unlikely the same amounts of contamination would have been included in the 3 different aliquots. Equally the data do not show evidence for  $^{37}\text{Ar}$  or  $^{39}\text{Ar}$  recoil. We interpret the isochron data as simple binary mixing lines between initial trapped components of atmospheric composition and K-correlated radiogenic components whose ages overlap ( $1\sigma$ ) with their associated plateau ages. The three  $^{40}\text{Ar}/^{39}\text{Ar}$  ages clearly date the same event and yield a weighted mean age of  $76.6 \pm 0.3$  Ma ( $2\sigma$ ) (Figure 3).

#### 4. Thermal Evolution of the Host Rock

[15] To determine the depth at which the pseudotachylytes were formed, we used a suite of thermochronological data to

<sup>1</sup>Auxiliary materials are available in the HTML. doi:10.1029/2011JB008846.

**Figure 5.** Thermal history of the pseudotachylyte-bearing Pyramid pluton (modern elevation  $\sim 3000$  m). Time-temperature path derived from: closed diamond - hornblende  $^{40}\text{Ar}/^{39}\text{Ar}$  ( $87.9 \pm 1.9$  Ma,  $2\sigma$ ); open diamond - biotite  $^{40}\text{Ar}/^{39}\text{Ar}$  ( $81.5 \pm 0.6$  Ma,  $2\sigma$ ); closed and open squares - measured zircon (U-Th)/He ages; closed circle - apatite fission track ( $67.2 \pm 6.6$  Ma,  $2\sigma$ , mean track length of  $13.96 \pm 1.15$   $\mu\text{m}$ ); and open circles - measured apatite (U-Th)/He ages (mean age =  $34.5 \pm 3.8$  Ma,  $2\sigma$ ). Individual (U-Th)/He ages shown with  $2\sigma$  uncertainty based on the reproducibility of the Durango (apatite, 6%) and Fish Canyon (zircon, 12%) age standards. The bimodal zircon age population is consistent with the observed zonation, with the younger population experiencing higher fractional He loss from the U enriched rims. Inverse modeling from thermochronological data performed using HeFTy [Ketchum, 2005] using the  $^{40}\text{Ar}/^{39}\text{Ar}$  ages to define the high temperature portion of the time-temperature curve, and the permitted time-Temperature path envelope shown as dark gray (50% confidence interval) and mid gray (95% confidence interval) zones. Model uses  $U_{\text{rim}}/U_{\text{core}} = 20$  for the zoned zircon population (younger age population).

constrain the post emplacement time-temperature ( $t$ - $T$ ) path of the host granodiorite.  $^{40}\text{Ar}/^{39}\text{Ar}$  (hornblende and biotite), zircon (U-Th)/He (ZHe), apatite fission track (AFT) and apatite (U-Th)/He (AHe) analyses are used to reconstruct the cooling history from  $\sim 550$  to  $60^\circ\text{C}$ . Ages were determined from samples collected 100–200 m from mapped fault traces at the same elevations at which the pseudotachylyte-bearing faults are exposed ( $\sim 3000$  m, see Figure 1).

[16] Single crystals of biotite and hornblende were harvested from crushed granodiorite using magnetic separation and handpicking under binocular microscope. Crystals were washed in DI and methanol, and analyzed alongside the

pseudotachylyte aliquots using the standard methodologies. The single crystal aliquots yielded age spectra and integrated ages within uncertainty of each other indicating a  $^{40}\text{Ar}/^{39}\text{Ar}$  hornblende age of  $87.9 \pm 1.9$  Ma ( $2\sigma$ ), while the single crystal biotite aliquot yielded an age of  $81.5 \pm 0.6$  Ma ( $2\sigma$ ), (Figure 4, data are included in the auxiliary material).

[17] Inclusion- and defect-free apatite and zircon crystals were hand-picked and each crystal loaded into a Pt foil tubes for (U-Th)/He analyses.  $^4\text{He}$  was determined by peak height comparison using a Hiden HAL3 spectrometer [Foeken *et al.*, 2006]. After degassing, the apatites were dissolved using standard techniques [Persano *et al.*, 2007] and the

<sup>a</sup>All analyses are of single crystal aliquots. For zircon analyses total analytical uncertainty is  $<3\%$  for apatite  $<2\%$ .  $F_T$  corrections are calculated after [Farley *et al.*, 1996] and [Hourigan *et al.*, 2005] assuming homogeneous U and Th distribution. ZHe ages fall into two groups, reflecting the strong relative rim enrichment in U observed in  $\sim 40\%$  of the zircon population using CL and fission track density variations (see the auxiliary material for detailed analysis). The remaining zircons exhibited CL zonation consistent with approximately homogeneous U distribution.  $F_T$  correction is therefore not valid for  $\sim 50\%$  of crystals. Inverse modeling was performed using the uncorrected (U-Th)/He ages (apatite and zircon) and step function zonation patterns (see text for details).

<sup>a</sup>Analyses by external detector method with dosimeter IRMM540 and  $\zeta = 277 \pm 9$  [Hurford and Green, 1983]. Fission tracks were revealed by etching in 5.5M HNO<sub>3</sub> for 20s at 21°C.  $\rho_s$  - spontaneous track density,  $N_s$  - number of spontaneous tracks,  $\rho_i$  - induced track density,  $N_i$  - number of induced tracks,  $\rho_D$  - track density of dosimeter,  $N_D$  - number of tracks from dosimeter,  $P(\chi^2)$  - chi squared probability that all single-crystal ages represent a single population, Dpar - mean diameter of fission track etch pits used to assess the composition of the apatites. MTL = mean track length, value in the bracket is the number measured.

zircon by Parr bomb acid digestion after Dobson *et al.* [2009]. U and Th determinations were made by isotopic dilution on an Agilent X ICP-MS.

[18] Zonation of U and Th in zircon is often highly variable, and can cause significant differences in the (U-Th)/He ages between individual crystals. SEM cathodoluminescence (CL) imaging was used to assess U and Th zonation in the zircon crystal population [Dobson *et al.*, 2008] (details are included in the auxiliary material). Inverse correlation of the CL intensity and the U concentration was confirmed using zircons included in the fission track mount. Approximately 20% of the zircon population exhibited essentially homogeneous CL zonation, and a further 40% showed narrow oscillatory zonation over the majority of the crystal volume. The narrow oscillatory CL zonation can be approximated by a homogeneous U concentration profile on the scale of He ejection [Hourigan *et al.*, 2005; Dobson *et al.*, 2008], and U and Th zonation will have minimal effect on the zircon (U-Th)/He ages of  $\sim 60\%$  of the population. The remaining 40% of the zircon population have a narrow 5–20  $\mu\text{m}$  rim of extremely low (zero) CL intensity and  $U_{\text{rim}}/U_{\text{core}} \gg 10$ . U rich rims cause an increased fractional loss of He by alpha-ejection, and zircon (U-Th)/He ages determined on these crystals will be significantly ( $\sim 10$ –20%) younger than those from the effectively homogenous population [Dobson *et al.*, 2008].

[19] The zircon (U-Th)/He ages fall into two groups at 58–62 Ma and 73–78 Ma (Figure 5 and Table 1). The zonation observed in the sample suggests that the younger population correspond to crystals with strong relative rim enrichment in U, and the older population correspond to crystals that exhibit CL zonation consistent with approximately homogeneous U distribution. Three apatite (U-Th)/He ages ranged from 31.6 to 37.2 Ma with a mean of  $53.8 \pm 5.9$  Ma (Table 1).

[20] Apatite fission tracks were revealed by etching in 5.5 M HNO<sub>3</sub> for 20s at 21°C, and the compositional control on annealing was monitored using Dpar (Table 2). The sample yielded AFT age of  $67.2 \pm 6.6$  Ma ( $2\sigma$ ), a mean track length of  $13.96 \pm 1.15 \mu\text{m}$  ( $2\sigma$ ,  $n = 62$ ), and a mean apatite (U-Th)/He age of  $34.5 \pm 2.8$  Ma ( $2\sigma$ ,  $n = 3$ ) (Figure 5, Tables 1 and 2).

## 5. Depth of Faulting

[21] Inverse modeling of the thermochronology data from the host rock was performed using HeFTy [Ketchum, 2005], using all the available <sup>40</sup>Ar/<sup>39</sup>Ar, (U-Th)/He and fission track data described above to provide the constraints on the model [Reiners *et al.*, 2004; Dobson *et al.*, 2010]. The younger (zoned) population of zircon (U-Th)/He ages was

modeled, using concentration profiles based on the CL images 5 $\times$ , 10 $\times$ , 20 $\times$  and 50 $\times$  rim enrichment [after Dobson *et al.*, 2008]. Figure 5 shows the  $t$ - $T$  path envelope for crystals with 20 $\times$  rim enrichment, which appears to be a minimum estimate of core-rim enrichment based on the observed track densities. For all modeled concentration changes, the form of the  $t$ - $T$  history envelope was unchanged but at lower levels of enrichment (5 $\times$ ) the temperature at which the system shifts from rapid to slow cooling increases by  $\sim 20^\circ\text{C}$ . In all instances, the  $t$ - $T$  histories support rapid ( $\sim 40^\circ\text{C}/\text{Myr}$ ) cooling to  $<150^\circ\text{C}$  by 80–75 Ma as the pluton was rapidly exhumed to a few kilometers depth immediately after intrusion (Figure 5). Subsequent slower cooling rates (average  $<10^\circ\text{C}/\text{Myr}$ ) from 70 Ma to the present reflect the general tectonic quiescence during the Paleogene [House *et al.*, 2001].

[22] Integrating the high precision pseudotachylyte formation age with the host rock  $t$ - $T$  history (Figure 5) shows that the ambient temperature at the time of SKF pseudotachylyte formation was between  $\sim 110$  and  $\sim 160^\circ\text{C}$ . The corresponding depth at those temperatures is a function of the geothermal gradient. Modern volcanic arcs have geothermal gradients exceeding  $40^\circ\text{C}/\text{km}$  [Rothstein and Manning, 2003], which would imply depths of 2.4 to 3.6 km. However, pluton emplacement in the Sierra terminated at  $\sim 80$  Ma, as subduction shallowed and migrated eastward. The associated crustal thickening is thought to have reduced the geothermal gradient rapidly [Dumitru, 1990]. Our thermochronological data indicate rapid cooling prior to  $\sim 75$  Ma ( $>40^\circ\text{C}/\text{Ma}$ ), with much lower cooling rates through the Cenozoic (generally  $<7^\circ\text{C}/\text{Ma}$ ). This is consistent with rapid readjustment of the geothermal gradient, synchronous with the exhumation of the pseudotachylyte-bearing rocks to within a few kilometers of the surface, by  $\sim 60$  Ma. At the time of pseudotachylyte generation the geothermal gradient is likely to have been 25 to  $30^\circ\text{C}/\text{km}$  [House *et al.*, 2001; Clark *et al.*, 2005] implying rupture depths of  $\sim 3.2$  to 5.8 km. While the inverse modeling supports a temperature of 110– $160^\circ\text{C}$  at  $\sim 77$  Ma (time of pseudotachylyte formation), it is possible that the ambient temperatures at the time of faulting were higher (a maximum of  $\sim 220^\circ\text{C}$  is also allowed by the model). However, the very rapid initial cooling followed by much slower subsequent cooling indicates that exhumation-derived cooling and the relaxation of the geothermal gradient were synchronous. This implies that if ambient temperatures at the time of pseudotachylyte formation were higher they were likely accompanied by a higher geothermal gradient and the depth of pseudotachylyte formation would still be within our calculated range. In the following analysis, we will consider the implications for pseudotachylyte generation in the depth

**Table 3.** Composition of Solidified Pseudotachylyte Measured by Wavelength Dispersive Sequential X-ray Fluorescence (WD-XRF) Equivalent to a Trachyandesite

range 2.4 km (minimum depth at 40°C/km) to 6.0 km (maximum depth at 25°C/km).

## 6. Melt Shear Resistance

[23] Following melting, the rheology of the slip zone transitions from sliding across a frictional contact to shearing of a viscous fluid in a layer between the wall rocks [Jeffreys, 1942; Fialko and Khazan, 2005]. Shear resistance in the melt layer is a complex function of melt viscosity, slip velocity and shear localization, which are all dependent on temperature and the duration of shearing [Fialko and Khazan, 2005; Nielsen et al., 2008, 2010a]. However, assuming a constant velocity gradient in the melt layer, the relationship between shear stress  $\sigma_m$  (Pa), slip velocity  $U_o$  (m/s), slip zone thickness  $H$  (m) and melt viscosity  $\eta$  (Pa s) can be approximated as

$$\sigma_m = \eta \frac{U_o}{H} \quad (1)$$

The shear resistance of the melt can therefore be estimated because slip zone thickness is measured in the field and in thin section, and slip velocity can be assumed to have been of the order of 1 m/s [Spray, 1993; Ujiie et al., 2007]. The viscosity of pseudotachylyte melts is controlled by melt composition, clast content and temperature, which must all be measured for reliable estimates of  $\eta$ .

[24] The pseudotachylyte composition was determined using wavelength dispersive sequential X-ray fluorescence (Table 3). Clast content and clast compositions were measured from SEM backscattered electron (BSE) images based on the gray scale value of each pixel (see Figure 2) following the method of Bjørk et al. [2009] (cf. Ray [1999] and Di Toro and Pennacchioni [2004]). Mineral phases that correspond to each gray scale value were determined using integrated energy dispersive X-ray (EDX). The area of pseudotachylyte analyzed was maximized using a mosaic of BSE images taken at the same magnification ( $\times 250$ ) and image capture conditions (brightness and contrast). Most clasts were fragments of cataclasite containing multiple mineral phases (Table 4). Mineral phases identified in monocrystal clasts were limited to quartz, Ca-rich plagioclase, orthoclase, Fe-oxides and titanite. Microcrystallites in the pseudotachylyte matrix have a composition similar to

plagioclase making it difficult to distinguish many of the clasts from the matrix based on gray scale value alone, so clast identification was completed manually. The minimum clast size that can be identified at the magnification is  $\sim 15 \mu\text{m}$ , though small clasts are likely under-sampled as they are difficult to distinguish from the texturally complex matrix. The pseudotachylyte sample used for  $^{40}\text{Ar}/^{39}\text{Ar}$  dating has a clast content of  $\sim 13.5\%$ .

[25] Peak temperature in the melt phase was determined from the survivor clast compositions [Spray, 1992, 2010]. The dominance of quartz, and prevalence of Ca-rich plagioclase feldspars over Na-rich plagioclase in the clast population is consistent with peak temperatures in excess of 1100°C, but the preservation of plagioclase requires temperatures not far in excess of 1150°C. The absence of pseudotachylyte partitioning into spherulitic and microlitic domains corroborates melt temperatures  $< 1450^\circ\text{C}$  [Di Toro and Pennacchioni, 2004], which is used in the viscosity calculation as an upper bound on temperature.

[26] Melt viscosities were calculated using Conflow [Mastin and Ghiorso, 2000; Mastin, 2002] which calculates the melt viscosity using the Shaw [1972] model for magmas with silica content less than 70 wt% by implementing the MELTS algorithm [Ghiorso and Sack, 1995] using a compilation of lab values for the thermodynamic properties. The effect of crystal content on the viscosity is incorporated using the Einstein-Roscoe equation [Marsh, 1981]. For the SKF melt composition, clast content and temperature under lithostatic stresses of 77 to 182 MPa and maximum water content bounded by the XRF LOI, melt viscosities ( $\eta$ ) would be in the order of 10 to 310 Pa s. Similar values for melt viscosity have been reported previously from a variety of pseudotachylyte faults [Spray, 1993; Ujiie et al., 2007].

[27] The low viscosities and order of magnitude variation are a direct result of the high temperatures inferred for the melt phase and the strong temperature dependence of the viscosity. In addition, the small amount of dissolved water inferred from the XRF LOI ( $\sim 2\%$ ) is sufficient to decrease viscosity by many orders of magnitude, contributing to the low values [e.g., Spray, 1993; Hess and Dingwell, 1996]. Our viscosity estimates assume Newtonian behavior for the bulk melt phase, which is unlikely given the melt contains suspended clasts. Our microstructural analyses show the pseudotachylyte has only 13.5% clasts so the effects of non-Newtonian behavior resulting from both clast content [Mueller et al., 2010] and clast shape [Mueller et al., 2011]

**Table 4.** Image Analysis Results of Measurements of Clast Content and Composition<sup>a</sup>

	Number of Clasts	Area of Clasts (pixels)
Original image	n/a	7086228
Quartz	326 (48.5)	395230 (5.6)
Mixed grains	47 (7.0)	366900 (5.2)
Plagioclase	228 (33.9)	160695 (2.3)
Albite	4 (0.6)	4426 (0.06)
Titanite/Fe-oxides	67 (10.0)	29011 (0.4)
Total grain values	672 (100)	956262 (13.56)
Matrix	n/a	6104080 (86.44)

<sup>a</sup>Results show the abundance of major mineral phases and mixed grains as proportion of total number of clasts identified and proportion of total area of clasts. Values in parentheses are percentages.

would have a negligible effect on bulk viscosity at the high strain rates characteristic of seismic slip rates.

[28] Using the calculated viscosities, typical slip velocities (1 m/s) and the observed thickness of the pseudotachylyte veins (0.25–10 mm), equation (1) shows that  $\sigma_m$  ranges from ~0.04 to 0.12 MPa ( $T = 1100^\circ\text{C}$ ,  $\eta = 310 \text{ Pa s}$ ) and ~0.001 to 0.04 MPa ( $T = 1450^\circ\text{C}$ ,  $\eta = 10$ ). Higher slip velocities do not alter the results significantly. These values of  $\sigma_m$  are comparable with those estimated from other seismogenic faults [Ujii *et al.*, 2007; Brodsky *et al.*, 2009]. Low shear resistance is consistent with low shear:normal stress ratios calculated from temperature measurements in boreholes drilled into seismically active faults [Kano *et al.*, 2006] and also with high velocity rock friction experiments in which melting of crystalline rock samples at near seismogenic conditions results in very low shear resistance [Di Toro *et al.*, 2006; Niemeijer *et al.*, 2011]. Additionally, theoretical models of shear resistance in the presence of melt consistently demonstrate that the presence of melt lubricates a fault, even in the case of thin melt layers partly supported by solid-solid asperity contacts [Nielsen *et al.*, 2010a, 2010b].

## 7. Discussion

### 7.1. Temperature and Depth of Pseudotachylyte Generation

[29] We have combined  $^{40}\text{Ar}/^{39}\text{Ar}$  dating of the pseudotachylyte in the SKF with the temperature-time history of the host rock to constrain the depth at which the pseudotachylyte formed. The thermal history indicates that the ambient temperature in the country rock at the time of pseudotachylyte formation was 110–160°C, implying that the depth at which the pseudotachylytes formed was less than 6 km. The compilation of pseudotachylyte reports in the literature by Sibson and Toy [2006] shows that 2.4 to 6 km is relatively shallow for pseudotachylyte formation, but not exceptional.

[30] Pseudotachylyte formation was accompanied by the formation of epidote and chlorite in adjacent cataclases, and some pseudotachylytes are altered to chlorite. Mineral assemblages containing predominantly chlorite and epidote, similar to those associated with the faults we describe, have previously been interpreted as representative of depths of faulting between 8 and 11 km in both the Sierra Nevada [Pachell and Evans, 2002; Griffith *et al.*, 2008] and the Adamello batholith, Italy [e.g., Di Toro and Pennacchioni, 2004]. Even in the absence of actinolite, chlorite and epidote assemblages are typically inferred to represent temperatures of 250 to 300°C [e.g., Guilbert and Park, 1986; Yardley, 1989], consistent with fluid inclusion constraints [Bruhn *et al.*, 1994]. Epidote-chlorite assemblages may also form at lower temperatures, and are reported from prehnite-pumpellyite facies conditions [Yardley, 1989]. However, the study area faults lack other low temperature minerals (e.g., zeolites), so the fault rock assemblage likely formed in excess of 250°C.

[31] The chlorite and epidote assemblage we describe is strictly limited to within faults, fractures and veins. Alteration halos accompany all of the mineralized features, defined by the hydrous alteration of plagioclase to sericite and hornblende and biotite to chlorite. Regionally, the primary igneous mineral assemblage is intact, and the bulk composition of the granodiorite is not altered. Hydrothermal

fluids focused in the faults and fractures therefore drove the chlorite-epidote mineralization; these minerals formed because of the presence of those fluids. Under these conditions externally buffered fluids controlled the composition of the alteration assemblage, and the temperature inferred from the hydrothermal assemblage reflects the fluid temperature.

[32] Our data show that advecting hydrothermal fluids passing through the faults were hotter than the surrounding rock. The thermochronology shows the host rock was at 110–160°C, whereas the hydrothermal mineral assemblage indicates the fluid temperature was probably greater than 250°C. The thermochronology does allow for ambient rock temperatures up to 220°C, suggesting the temperature difference between the rock and hydrothermal fluid could have been relatively small. However, the observation of hot hydrothermal fluids compared to the surrounding rock is consistent with temperatures associated with epidote and chlorite mineralization measured in geothermal systems that reach several hundreds of degrees at depths of <1 km [e.g., Bird and Spieler, 2004, and references therein]. Exhumed hydrothermal systems show epidote and chlorite precipitating at paleo-depths of less than 4 km around granitic intrusions [e.g., Dilles and Einaudi, 1992] so hydrothermal assemblages forming at temperatures greater than would be predicted from geothermal gradients are observed. Anomalous high temperature fluids are characteristic of hydrothermal systems in and around intrusive bodies. It follows that hydrothermal mineral assemblages may indicate temperatures that are significantly different to the surrounding country rock and inferring the ambient temperature at the time of faulting from hydrothermal assemblages is problematic.

### 7.2. Stress Drop Variability

[33] The depth constraints provide information regarding the stress on the fault at the initiation of slip. The resolved shear stress resulting in failure on the fault at the time of rupture nucleation,  $\sigma_0$ , can be calculated by assuming the intermediate principal stress,  $\sigma_2$ , was vertical, consistent with the strike-slip offset across the SKF and other study area faults [Sibson, 1974]. For an average rock density of 2800 kg/m<sup>3</sup>, rupture depths of 2.4 and 6 km equate to lithostatic stresses of 66 MPa and 165 MPa, respectively. Failure of optimally oriented strike-slip faults at these depths with  $\sigma_2$  equal to the lithostatic stress, setting  $\sigma_2$  equal to the mean of  $\sigma_1$  and  $\sigma_3$  (following Sibson [1974]), Byerlee friction of 0.75 and hydrostatic pore pressures, requires  $\sigma_0$  to be 21–51 MPa [Sibson, 1974, 1985].

[34] The failure stress values are several orders of magnitude greater than the shear resistance of the pseudotachylyte fault veins estimated in Section 6. Assuming uniform failure stress,  $\sigma_0$ , stress drop in the pseudotachylyte-bearing parts of the fault,  $\Delta\sigma_m$ , is given by  $\sigma_0 - \sigma_m$ . Because the resisting stress in the pseudotachylyte-bearing parts of the fault is negligible (for all possible depths and melt temperatures),  $\Delta\sigma_m$  is the same magnitude as the static failure stresses (21–51 MPa). These results suggest that the stress drop over those patches of the faults that melted was complete, which is in agreement with theoretical expectations [Fialko and Khazan, 2005; Nielsen *et al.*, 2008]. Pore pressures exceeding hydrostatic values at the initiation of slip could have reduced  $\sigma_0$ , and consequently  $\Delta\sigma_m$  but there is no

**Figure 6.** Plot showing the proportion of the fault that would have melted for macroscopic stress drops ( $\Delta\sigma$ ) of 1, 5 and 10 MPa. Dashed curves are failure stress of 21 MPa (rupture depth = 2.4 km), solid curves 51 MPa (rupture depth = 6 km). The macroscopic mean stress drop ( $\Delta\sigma$ ) is averaged over the fault area as described in equation (2). Shear resistance of the melts in this plot are assumed to be 0.2 MPa, the highest value obtained in our analysis, lower values will result in smaller proportions of melting.

field evidence for hydrofracture in the Kings Canyon faults (indicative of high pore pressures), and the observation that melt formed suggests fluid pressures were low during slip.

[35] This estimate of  $\Delta\sigma_m$  is for the coseismic, dynamic stress drop accompanying melting, although if the quench time of the melt is much longer than the duration of rupture, then  $\Delta\sigma_m$  is also the local static stress drop. Seismological estimates of the dynamic stress drop are challenging as they rely on either extreme near-field data or model-dependent interpretations of far-field data. Nonetheless, most studies have found that dynamic stress drops averaged over a complete rupture are commonly  $\sim 1$  MPa and do not exceed 10 MPa [Brune, 1970; Heaton, 1990; Beeler *et al.*, 2003; Malagnini *et al.*, 2010]. The seismological studies also indicate that averaged over the rupture, the dynamic stress drops are comparable to the static stress drops [Kanamori and Anderson, 1975], even though theoretical and laboratory studies do suggest plausible re-strengthening processes [Del Gaudio *et al.*, 2009; Nielsen *et al.*, 2010b].

[36] Reconciling the seismological and the geological observations requires incorporating the heterogeneity of stress conditions on the rupture to connect the rupture-averaged stress drop value to local values. The heterogeneous distribution of fault rocks, in particular pseudotachylytes, along the study area faults indicates complexity in the stress changes at the exposure scale.

[37] The pseudotachylyte patches in the SKF and other faults in the study area are  $\sim 5$  to 10 m long and formed within larger ruptures [Kirkpatrick and Shipton, 2009]. If the

paleo-seismic events that formed the pseudotachylytes in the study area conformed to historically recorded typical macroscopic dynamic stress drops,  $\Delta\sigma$ , the extremely high  $\Delta\sigma_m$  values must be balanced by low stress drops in the non-melted portions of the fault,  $\Delta\sigma_r$ . The results therefore imply that rupture-averaged dynamic stress drops were dominated by processes operating over small areas of the fault plane. They also suggest that small-scale heterogeneity in dynamic stress drop is characterized by the lengths of the pseudotachylyte patches (i.e., of the order of a few meters to  $\sim 10$  m). A similar interpretation was suggested from measurements of coseismic slip on faults that form in single-jerk events where spatial fluctuations in slip indicate variations in stress drop [e.g., McGarr *et al.*, 1979], but limited offset markers restrict the potential for quantifying the length scale over which variations occurred.

[38] The magnitude of stress drop variation is a function of the spatial distribution of pseudotachylytes in the fault. The balance between the stress drop in the melt, the stress drop in the non-melted parts and the macroscopic stress drop is a simple spatial average given by

$$\Delta\sigma = \Delta\sigma_r(1 - x) + \Delta\sigma_mx \quad (2)$$

where  $x$  is the proportion of the fault that melted. Using our lowest estimates of  $\Delta\sigma_m$  (highest  $\sigma_m$ ) and macroscopic dynamic stress drops ( $\Delta\sigma$ ) of 1, 5 and 10 MPa from seismological observations, we estimate the proportion of the fault that would have melted during the SKF paleo-earthquake for a range of possible  $\Delta\sigma_r$  values (Figure 6). The maximum amount of melting during the paleo-earthquake on the SKF would be  $\sim 50\%$  which occurs for the rupture depth of 2.4 km,  $\Delta\sigma = 10$  MPa and  $\Delta\sigma_r = 0$ . The maximum depth constrained by the thermochronology is 6 km (i.e.,  $\Delta\sigma_m \sim 51$  MPa), for which equation (2) predicts that a maximum of  $\sim 19\%$  of the fault would have melted. This is more consistent with the qualitative field observations, and suggests greater depths implied by lower geothermal gradients are more likely than shallow rupture depths. Note that higher  $\sigma_m$  values would require smaller  $\Delta\sigma_m$  and consequently the predicted proportion of the fault that melted would increase, which is inconsistent with the field observations. Since the shear resistance during slip is effectively negligible, the result is not excessively rheology dependent as the melt resistance is much lower than the stress at failure.

[39] The high  $\Delta\sigma_m$  values imply that the dynamic stress drop varied spatially by at least an order of magnitude during a single rupture. As some melting evidently occurred during the earthquake,  $\Delta\sigma_r$  must have been less than 10 MPa, and could have been significantly lower. Such large stress variations during earthquake rupture have previously been inferred to explain near-source strong ground motions [e.g., Kostrov, 1974], but without direct observation of the processes causing the variation. Spatially variable dynamic stress drop also requires that dynamic weakening in the non-melted parts of the fault was small, or that significant healing characterizes the final increments of slip in the non-melted parts of the rupture area. However, the fault rocks contain little information regarding the distances over which the dynamic stress drop changed from large to small. The pseudotachylytes pinch out along-strike into cataclases,

thinning gradually over a few cm. If the dynamic stress drop switched abruptly from complete to very little over a few cm, the step-changes in the stress drop of the order of tens of MPa would require failure of the surrounding rock, which is not observed in the field. It is more likely that the spatial variation in stress drop occurred more gradually over meters or more, perhaps modulated by the stiffness of the surrounding rock. This requires that in some places the stress drop in the cataclasites was large (i.e., immediately adjacent to pseudotachylyte patches), but on average the stress drop in the cataclasites must have been small.

[40] In many respects, the study area faults are classic examples of pseudotachylyte generating faults [Sibson and Toy, 2006]. They cut low porosity, quartz-rich, crystalline rocks and were active at shallow to mid crustal depths. Pseudotachylytes are less often identified in exhumed plate boundary faults, which typically contain gouge and cataclase without evidence for melting. It is interesting to note that the maximum proportion of the Sierra faults that could have melted is  $\leq 50\%$  (Figure 6), and was likely  $< 20\%$ ; another reason for the apparent scarcity of frictional melt products in exhumed faults (in addition to previously discussed factors [Griffith *et al.*, 2008; Kirkpatrick *et al.*, 2009]) is that only a small area of any earthquake rupture would melt reducing the likelihood of finding pseudotachylytes in an exposure of an exhumed fault.

[41] The distribution of deformation products in the exhumed SKF fault reflects the spatial variation in coseismic source parameters. The key control on the onset of melting was the architecture of the fault. Melting occurred where meso-scale ‘asperities’, or bumps, on either side of the fault were locally in contact. At this place on the fault, the thickness of the slip zone [Kirkpatrick and Shipton, 2009] was narrow, and normal stresses were likely higher [Chester and Chester, 2000; Griffith *et al.*, 2010]. Where the slip zone is narrow, frictional heating raised the temperature quicker and resulted in melting after smaller amounts of slip than where it is wider. Higher stresses at the asperity may have caused more rapid frictional heating. This resulted in diverging stress trajectories for the melted and non-melted parts of the fault. As faults from a variety of lithologies and tectonic settings have similar roughness at the scales of seismic slip [e.g., Sagy *et al.*, 2007; Brodsky *et al.*, 2011], we expect that slip zone thickness would vary with similar properties on a wide range of faults. Therefore, we predict that the onset of any thermally activated weakening mechanism [Di Toro *et al.*, 2011] will be spatially variable in the same way as suggested by the pseudotachylyte patches and that the pattern of small proportions of a rupture area experiencing high stress drops is common.

[42] Constraints on earthquake source parameters can be obtained by parameterizing the fault plane and inverting seismic data for slip and moment release histories [e.g., Bouchon, 1997; Ma *et al.*, 2001]. Numerous studies show that the seismic source is complex [e.g., Hanks, 1979], but there are few constraints on the degree of complexity at short length scales because attenuation of seismic energy and scattering from structural heterogeneity in the shallow crust limits the spatial resolution of these inversions to kilometers. Variations that occur over shorter length scales are not deterministically imaged by seismological source inversions. The results of this study show that fault architecture and

the distribution of fault rocks can be used to constrain the physics of earthquake rupture at length scales below the resolution of seismic inversions.

## 8. Conclusions

[43] Integrating  $^{40}\text{Ar}/^{39}\text{Ar}$  dating of pseudotachylytes and the time-temperature path of the host rock shows that the depth of pseudotachylyte formation in the study area faults was 2.4 to 6 km. At these depths, the stress at failure was up to  $\sim 51$  MPa for optimally oriented faults. As the shear resistance of the melt layers was  $< 1$  MPa, the dynamic stress drop associated with pseudotachylyte formation was complete suggesting stress drops of similar magnitude to those measured experimentally do occur during earthquakes. By considering the macroscopic estimates of dynamic static stress drop measured seismologically, we have demonstrated that at mid crustal conditions the dynamic stress drop over melt bearing and non-melt bearing parts of the fault differs by at least an order of magnitude. We conclude that the extent of pseudotachylytes exposed in exhumed faults represent the minimum length scale over which seismic source parameters vary, i.e., 1 to 10 m. Although it has long been known that stress must be highly heterogeneous during earthquakes, the pseudotachylyte observations combined with the depth constraints provide a quantitative estimate of the degree and scale of heterogeneity.
