ABSTRACT

1
2
3
4
5 The Samnites were an Iron Age population that shifted from warlike mountain
6 dwellers to the largest sociopolitical unit of central Italy, able to dispute with Rome the
7 domination over the peninsula. Archaeological and historical evidence suggests that this
8 major shift in the scale of conflict may have involved a reorganization of the military system,
9 which changed from an elite militia to a conscript or standing army from the Orientalizing-
10 Archaic (800-500 BC) to Hellenistic times (400-27 BC). We propose a bioarchaeological
11 framework jointly analyzing skeletal properties and funerary treatment in male Samnites to
12 investigate on this shift in military organization. We anticipated that, when Samnites had an
13 elite militia, the warring force was constituted by the wealthier segments of the society.
14 Conversely, we expected the warring force of the standing/conscript army to be mainly drawn
15 from the lower social strata. We considered high asymmetry in J, a measure of humeral
16 torsional rigidity (calculated via cross-sectional geometry, CSG) as a proxy for pre- and peri-
17 adolescent-onset weapon training. The social standing of the individual was approximated via
18 funerary treatment analysis (Status Index). Results show that in the Orientalizing –Archaic
19 period, humeral asymmetry and Status Index are positively correlated, and the high-status
20 subsample shows significantly higher asymmetry than the low-status subsample. Among
21 Hellenistic Samnites, no correlation between Status Index and humeral asymmetry is present,
22 and the low-status subsample is the most lateralized.

1
2
3 Warfare in prehistory and the relationship between war and social complexity is an
4
5 issue that has long intrigued scholars in human disciplines (Keegan, 1993; Keeley, 1996;
6
7 Kelly, 2000; Otterbein, 2004; Guilaine and Zammit, 2005; Martin et al., 2012). Stein (2001)
8
9 noticed that investigations of past social change have been rare because it is difficult to
10
11 identify power relationships in the archaeological record. He proposes to do so by integrating
12
13 textual and iconographic sources with material evidence. Bioarchaeology, through the joint
14
15 analysis of skeletal data and archaeological information (and historical sources, when
16
17 available), provides a powerful tool to test hypotheses on environmental and social changes
18
19 that are expected to have had biological consequences. The main source of raw data used to
20
21 create an empirical link between warfare and skeletal properties has been the study of past
22
23 trauma and paleopathology (Walker, 2001). Recently, this kind of data has been studied in
24
25 strong theoretical frameworks that allowed for the investigation of complex sociopolitical
26
27 processes (Glencross, 2011; Martin et al., 2012; Pérez, 2012; Robbins Schug et al., 2012;
28
29 Tiesler and Cucina, 2012; Knüsel and Smith, 2014a,b). Skeletal injuries can provide evidence
30
31 of the occurrence of armed violence, and the archaeological context can allow for a distinction
32
33 between individuals that were victims or perpetrators of violence. However, preserved
34
35 injuries are inherently rare in the skeletal record, and the identification of warriors is often not
36
37 straightforward. Perez (2012) introduced the concept of ‘politicization of the dead’ and
38
39 suggests that the manipulation of the corpse may provide information on the communities at
40
41 both ends of violence. There are various ways in which the body is ‘culturally shaped’ by the
42
43 practices and behavior of the group in life as well as in death. One of those ways may be the
44
45 early onset and frequent practice of unimanual weapon training, which results in high levels
46
47 of asymmetry in humeral torsional rigidity (J, calculated via cross-sectional geometry, CSG;
48
49 Churchill and Rhodes, 2009; Sparacello et al., 2011). Bioarchaeological and experimental
50
51 evidence demonstrates that high humeral lateralization in J is common in past and modern
52
53
54
55
56
57
58
59
60

1
2
3 groups whose shared behavioral repertoire included frequent and stressful unimanual tasks
4
5 like asymmetric sports and throwing activities (Trinkaus et al., 1994; Churchill et al., 1996,
6
7 2000; Shaw and Stock, 2009). Bone epigenetic functional adaptations have the advantage of
8
9 not being episodic, but expected in a non-pathological setting when stressful, highly
10
11 characterizing activities are practiced since pre-adolescence (Pearson and Lieberman, 2004;
12
13 Ruff et al., 2006). We analyze asymmetry in humeral torsional rigidity in the context of a shift
14
15 in sociopolitical organization of an Iron Age population, which is likely to have involved a
16
17 change in military organization from a small aristocratic militia to a large army. We test the
18
19 hypothesis that this shift in military organization caused the widespread use of weapons to
20
21 shift through time from the elite segment of the society to the lower social strata.
22
23

24 25 **Archeological and historical background**

26
27 The European Iron Age (from about 1000 BC to Roman Conquest, depending on the
28
29 population under exam) was a time of demographic growth, intensification of agriculture, and
30
31 increasing sociopolitical complexity (Peroni, 1989, 1992; Cunliffe, 1994, 2008; Guidi, 2000;
32
33 Boatwright et al., 2004). In the Mediterranean, early states based on elected representatives
34
35 were developing from simpler forms of stratified social organization based on kinship ties,
36
37 which can be generally referred to as chiefdoms (Earle, 1997; Barker et al., 1996; Kristiansen,
38
39 1998, 1999; however we are not operating in a strict social evolutionary model here, see
40
41 Pauketat, 2007). One of those shifts in power relationships is believed to have happened
42
43 among the Samnite people of central Italy with the passage from the Orientalizing-Archaic
44
45 period (c. 800-500 BC) to the Hellenistic period (c. 400-27 BC). The term ‘Samnites’ was
46
47 used by ancient Roman and Greek historians to identify numerous Oscan-speaking groups
48
49 which called themselves ‘Safineis’ (in addition to other names specific to their sociopolitical
50
51 unit, e.g. Pentri, Irpini, Vestini, and several others), and who migrated into central Italy
52
53 probably during the Bronze Age (La Regina, 1989).
54
55
56
57
58
59
60

1
2
3 A few historical accounts describe Oscan people of the Orientalizing-Archaic period
4 as 'isolated mountain dwellers' known for their proclivity to raid neighbors (Salmon, 1967;
5 Tagliamonte, 1994, 1997, 1999, 2009). By the Hellenistic period (400-27 BC), Samnites
6
7 become one of the largest political and military powers of the Italian peninsula, and were able
8 to dispute with the Roman Republic the hegemony over central Italy (La Regina, 1968;
9 Tagliamonte, 1997). In addition to this change in the scale and scope of conflict,
10
11 archaeological and historical evidence strongly suggests that Samnites experienced profound
12 changes in sociopolitical organization.
13
14
15
16
17
18
19

20
21 In the Orientalizing-Archaic period, burials presumably belonging to the social elites
22 were characterized by the presence of warrior paraphernalia (swords, javelins, and protective
23 gears) and banqueting sets (pitchers, serving platters, skewers, and andirons; Tagliamonte,
24
25 1997, 1999). The association between social standing and warlike prowess is also suggested
26 by iconographic evidence, such as the statue of the Warrior of Capetrano (c. 6th century BC),
27
28 a warrior-leader or king, which is depicted with a sword, a couple of spears, and an axe, as
29 well as wearing defensive gears (d'Ercole, 1990; Calderini et al., 2007; d'Ercole and Cella,
30
31 2007a,b). Also burial spatial patterns suggest the rise of permanent elites based on kinship
32 (Barker et al., 1996; Tagliamonte, 1997; Bietti-Sestieri et al., 2000). The joint analysis of
33
34 skeletal remains and funerary treatment evidences an unequal distribution of wealth among
35 several grave circles, which represented different patrilinear lineages (Bondioli et al., 1986;
36
37 Rubini, 1996). This suggests the development of stable hierarchies in which the power was
38 held by an aristocracy that was legitimized by extended kin coalitions (d'Ercole, 1990;
39
40 d'Ercole et al., 2003). Small-scale conflict between neighboring communities within the
41
42 Samnite stock was common, as suggested by ancient historical accounts and by the high
43
44 incidence of sword injuries and cranial trauma in many Orientalizing-Archaic necropoli,
45
46 especially in males (Macchiarelli et al., 1981; Robb, 1997; Paine et al., 2007).
47

50
51
52
53
54
55
56
57
58
59
60

1
2
3 In the Hellenistic period, weapons disappear from grave assemblages. In chamber
4
5 tombs, presumably pertaining to the social elites, banqueting sets are now accompanied by
6
7 items related to gymnastic activity (metal tools to scrape the body from sweat and sand, and
8
9 ointment containers), culture (inkpots and pen-nibs), and leisure (dices, gaming pawns;
10
11 Copersino and d'Ercole, 2003). Historical accounts report that Samnites by this time
12
13 functioned as a highly decentralized, democratic state, composed of hierarchically-organized
14
15 and elected administrative units (Salmon, 1967; La Regina, 1989; d'Ercole, 1990;
16
17 Tagliamonte, 1997). During times of war – which were very frequent and included three
18
19 major wars with Rome (the Samnite Wars, 343-290 BC) – leadership was unified and power
20
21 exerted by the Samnite League, a central political and military entity that confederated the
22
23 Oscan-speaking tribes (Lepore, 1989, 1992; Tagliamonte, 1994). After the Samnite Wars, the
24
25 Roman Republic imposed a truce of subordination but substantial independence (*civitas sine*
26
27 *suffragio* status). However, Samnites were still able to mobilize armies that sided against the
28
29 Roman Republic during the Pyrric War (280-275 BC), the Second Punic War (218-201), the
30
31 Social War (91-89 BC), the Silla-Marius Civil War (82 BC), the Rebellion of Spartacus (73-
32
33 71), and even the Catiline Conspiracy (62 BC). Samnites were finally assimilated into the
34
35 newly-formed Roman Empire in 27 BC (La Regina, 1968; Tagliamonte, 1997).
36
37
38
39
40

41 The major change in the scale, frequency, and degree of organization of warfare that
42
43 accompanied the shift in sociopolitical organization is believed to have had a major impact on
44
45 military organization. The wars of the Hellenistic period were fought by large-scale armies
46
47 fighting pitched battles for the purpose of territorial conquest (Bradley, 2000; Boatwright et
48
49 al., 2004). Before this date, scholars suggest that simpler and less structured forms of warfare
50
51 prevailed, consisting of raiding and looting nearby communities for revenge, booty, or social
52
53 and political prestige (Salmon, 1967; Boatwright et al., 2004; Claessen, 2006). In the
54
55 Orientalizing-Archaic, it is believed that access to the army was limited to the social elites,
56
57
58
59
60

1
2
3 because only wealthy individuals could afford to maintain the expensive gear for waging war
4
5 (Hammond, 1959; Hanson, 1989; Otterbein, 2004). During this time, warriors served as
6
7 followers of an aristocratic leader who had organized the enterprise (Boatwright et al., 2004).
8
9 Conversely, the large standing or conscript armies that were necessary for greater-scale
10
11 expansionistic warfare drew the bulk of the warring force from the lower social strata
12
13 (Otterbein, 1970; Claessen and Skalnik, 1978). Such transition has been best historically
14
15 documented for Rome: in the fifth century BC, social organization changed from a monarchy
16
17 to a republic, and by the fourth century legionaries started to receive a daily stipend (Bradley,
18
19 2000; Boatwright et al., 2004).
20
21

22 **Purpose of the research**

23
24
25 It appears that there was a difference in which social strata waged war between the
26
27 small aristocratic militia and in large standing armies typical of states. Based on
28
29 archaeological and historical evidence and analogies with the Greek and Roman societies, we
30
31 presume that in the Orientalizing-Archaic period Samnites had a small aristocratic militia, and
32
33 developed a conscript or standing army in the Hellenistic period. When diachronically
34
35 analyzing the skeletal properties of Samnites across social strata, we expect to be able to
36
37 detect this shift in military organization. We propose a bioarchaeological research framework
38
39 where high humeral asymmetry in torsional rigidity is used as a proxy for the pre- and peri-
40
41 adolescent onset of weapon training (at the time, swords were single-handed, and the javelin
42
43 was the most important weapon), and a numerical index calculated from grave good richness
44
45 (the Status Index, see below) is a rough proxy for social standing. We therefore expect: 1) a
46
47 significant positive correlation between humeral bilateral asymmetry and Status Index in the
48
49 Orientalizing-Archaic. When dividing the Status Index in categories, the subsample of
50
51 individuals with higher status should show a significantly higher average humeral asymmetry
52
53
54
55
56
57
58
59
60

1
2
3 when compared to the subsample of individuals with lower status; 2) the correlation should
4
5 disappear, or change sign, when analyzing Hellenistic skeletal series.
6

7 8 **MATERIALS AND METHODS**

9
10 The 361 male individuals included in this study belong to 11 Orientalizing-Archaic
11 and Hellenistic necropoli (Table 1) falling within the territory of Abruzzo (central Italy,
12 Figure 1). Ten necropoli are located in close proximity to each other in the Aterno River
13 Valley; one, Alfedena, is c. 50 Km south (Figure 1). The Aterno River Valley necropoli
14 belong to the Vestini people, while Alfedena was settled by the Pentri people. Both people
15 belonged to the Oscan ethno-linguistic group, and were part of the later Samnite League.
16
17
18
19
20
21

22 [Insert Figure 1 and Table 1 about here]
23
24

25 The Aterno River Valley skeletal series are preserved in the museum ‘Musé’ at Paludi
26 di Celano (Avezzano), Abruzzo Region. The Alfedena skeletal series is preserved in part in
27 the museum ‘Museo di Antropologia Giuseppe Sergi - Polo Museale Sapienza’ (Rome), Lazio
28 Region, and in part at the Università de L’Aquila (L’Aquila), Abruzzo Region. Most of the
29 necropoli have been excavated in the last decades, and anthropological data have been the
30 focus of several Master’s and Doctoral Theses (Piccirilli, 1999; Bestetti, 2002; Ridolfi, 2002;
31 Melandri, 2005; Napolitano, 2012; Sparacello, 2013), but are largely unpublished except for
32 Fossa (Cosentino et al., 2001; Copersino and d’Ercole, 2003; d’Ercole and Benelli, 2004) and
33 Alfedena (Coppa et al., 1981; Paine et al., 2007; Sparacello et al., 2011). The individuals
34 included constitute the totality of the specimens preserving at least a fragment of both humeri
35 which was appropriate for the CSG analysis.
36
37
38
39
40
41
42
43
44
45
46
47
48

49 **Cross-Sectional Geometry**

50 We employed the Cross-Sectional Geometry (CSG) method to reconstruct activity-
51 influenced functional adaptations of Samnite’s upper limb. The method is based on the theory
52 that bone tissue responds dynamically to bending stresses and strains to optimize itself to its
53
54
55
56
57
58
59
60

1
2
3 mechanical environment (Lovejoy et al., 1976; Lazenby, 1990; Pearson and Lieberman, 2004;
4
5 Ruff et al., 2006; Ruff, 2008). The size and shape of the cross-sections of long bones can be
6
7 therefore analyzed through the same principles used by engineers in designing structures, in
8
9 this case hollow beams. It has been shown that cross-sectional properties inform on the
10
11 prevalent mechanical environment of an individual (Ruff et al., 2006), and are particularly
12
13 sensitive to activities performed at pre- and peri-pubescent ages (Pearson and Liebermann,
14
15 2004). The integration of quantitative data derived from CSG with archaeological information
16
17 has been used to make inferences about the subsistence strategies, and mobility levels of past
18
19 populations (e.g. Larsen, 1995, 1997; Holt, 2003; Stock, 2006; Marchi et al., 2006, 2011).
20
21 However, we agree that a cautious approach to CSG data interpretation is advisable, and that
22
23 important caveats – mainly related to sample size and to the ontogenetic phase on which
24
25 bones are most responsive to activity – need to be addressed before making inferences about
26
27 ‘habitual’ activities of past populations (Meyer et al., 2011; Jurmain et al., 2012).
28
29
30
31

32 Cross sections were reconstructed in a non-invasive manner using the SolidCSG
33
34 method (Sparacello and Pearson, 2010), a modified version of the Latex Cast Method (O’Neil
35
36 and Ruff, 2004), based on periosteal molds and regression equations (Stock and Shaw, 2007;
37
38 Sparacello and Pearson, 2010; Macintosh et al., 2013). The CSG variable analyzed here is the
39
40 polar second moment of area J , which corresponds to the torsional and (twice) average
41
42 bending rigidity of the shaft. Polysiloxane molds of the periosteal contour were taken at mid-
43
44 distal humerus (35% bone length from the distal end), using bone lengths defined by Ruff
45
46 (2002). When possible, prior to taking periosteal molds, bones were positioned according to
47
48 the appropriate reference axes (Ruff, 2002). When length could not be estimated but the distal
49
50 portion of the humerus was available, the level corresponding to 35% of bone length was
51
52 approximated as the midpoint between the most proximal extension of the medial and lateral
53
54 epicondyles, and the most distal extension of the deltoid tuberosity.
55
56
57
58
59
60

1
2
3 The effect of inaccurate location of the section on the error ranges of femoral and
4 tibial cross-sectional parameters has been explored in previous research (Sládek et al., 2010).
5
6 The authors found a greater influence of inaccurate positioning on tibial J than on femoral J.
7
8 In order to be reasonably accurate, the estimated location of the midshaft tibial section should
9
10 be determined within a maximum range of 1.4 cm from the actual section. However, this is
11
12 mainly due to the rapid longitudinal changes in size and shape along the tibia, because for the
13
14 more regular femur the range increases to 7.4 cm. A similar study has not been yet performed
15
16 on the humerus. However, the portion of the humeral diaphysis where we estimated the
17
18 location of the section is not subject to significant changes in area or shape, because it is not
19
20 influenced by the epicondyles or by the deltoid tuberosity. We evaluated the amount of
21
22 change in J across the humeral shaft from the section placed at 30% of the humeral length to
23
24 the section placed at 40% of humeral length in 20 modern humeri (data from pQCT scans
25
26 provided by Colin Shaw). The mean change in J between the 30% and 40% sections is 7.11%.
27
28 This value is an estimate of the maximum error possible in the determination of J. We expect
29
30 the error in humeral bilateral asymmetry to be lower for two reasons. First, the 30% and 40%
31
32 sections are often influenced by the epicondyles and by the deltoid insertion, respectively.
33
34 The 35% section falls in a portion of the diaphysis where there is no direct muscle activity,
35
36 and it is typically the location where the bone is most constricted in circumference and
37
38 experience minimal longitudinal variations in shape and area. Second, the difference in the
39
40 estimated position of the section between the right and left humeri has been minimized by
41
42 placing side by side the two fragments of humeral diaphyses during data collection. We
43
44 believe that estimating the level of the section in this setting is a reasonable approximation in
45
46 order to maximize sample size. Results obtained by excluding the individuals for which the
47
48 position of the cross section was estimated will be provided.
49
50
51
52
53
54
55
56
57
58
59
60

1
2
3 Individuals under exam were characterized based on their degree of humeral bilateral
4
5 asymmetry in J. Humeral bilateral asymmetry was calculated using the formula $[(J_{\max} -$
6
7 $J_{\min})/J_{\min}] \times 100$ following previous studies (Rhodes and Knüsel 2005; Sparacello and Marchi
8
9 2008; Sparacello et al. 2011).

11 **Status analysis.**

12
13
14 Burials are widely used in archaeology to make inferences about wealth, status, and
15
16 role of the deceased individual, as well as to make interpretations of the political structure of
17
18 past societies (Saxe, 1970; Binford, 1971; Peebles, 1971). However, it is problematic to make
19
20 a direct inference on the world of the living by looking at the way they treated their dead.
21
22 Various studies have explored how funerary symbolism may be misleading due to the
23
24 complex factors that mediate between status in life and treatment in death (Ucko, 1969;
25
26 Hodder, 1980, 1982; Parker-Pearson, 1982; Shanks and Tilley, 1982; Samson, 1987; Morris,
27
28 1992; Brown, 1995). Moreover, not all the aspects of social organization are equally likely to
29
30 be reflected in the archaeological record of burials (O'Shea 1981, 1984). In addition to
31
32 theoretical problems, the nature of burial data is fragmentary (not all the grave goods
33
34 preserve) and selective (not all the individuals are buried) (Härke, 1997). The inference on the
35
36 social status of an individual based on grave goods may be therefore biased by assumptions
37
38 that are not entirely testable, and only general inferences can be made.
39
40
41
42

43 With all the above caveats in mind, in this study we employed a simple way to obtain
44
45 what we posit is a correlate of the social status of the individuals: the Status Index (SI),
46
47 calculated from the list of grave goods associated with the burial (Bernabei et al., 1995;
48
49 Cuozzo, 2003; D'Andrea, 2006; Melandri, 2010). Given the differences in grave goods
50
51 composition, the SI was calculated separately for the Orientalizing-Archaic and the
52
53 Hellenistic period (Sparacello, 2013). Grave goods were divided in simple functional
54
55 categories (k) (e.g. weapons, grilling equipment, banqueting equipment, food containers, pins
56
57
58
59
60

and brooches); for each burial (h), the SI is calculated by multiplying the number of items (N) in each category for its Coefficient of Status (Cs), and then by making the sum of the value obtained for all categories that are present in the grave (Sum Type method):

$$SI(h) = \sum(k) [N_k \times Cs(k)].$$

The Coefficient of Status takes into account how rare a category is, and how many other items are present in the grave where the category was found. As a result, it weights the importance of a category in determining how 'elite' a burial was. A coefficient is calculated first for each category in each burial. If $N(k)$ is the number of burials that contain the k category, and $N(hk)$ is the number of items present in a burial that contains that category, the Coefficient of Status of k in each burial h is calculated as:

$$Cs(hk) = [N(hk)/N(k)].$$

The Coefficient of Status of a category k for the whole sample is calculated by summing the coefficients calculated for each burial:

$$Cs(k) = \sum(h) [N(hk)/N(k)].$$

The raw data on the frequencies of each category in each burial, as well as the matrices with the calculation of the Status Index are available in Sparacello (2013). We used the Sum Type method to calculate the Status Index (rather than the Richest Type method) due to the simple categories we used, which did not take into account whether a particular item was a 'prestige item', i.e. finely crafted or imported. This lack of precise determination of the qualitative nature of grave goods means that a significant portion of possible information on 'richness' may have been overlooked. A typological analysis of each grave good would likely give a more accurate depiction of the level of prestige associated with a burial. Moreover, a comprehensive analysis of the context of the funeral rite might give information on the relative importance of certain categories, allowing for the calculation of a weighted Coefficient of Status (Cuozzo, 2003). However, these studies have not been performed yet for

1
2
3 most of the necropoli included in this research. Future analyses and interpretations could
4
5 certainly benefit from a more detailed assessment of the quality of the items used to estimate
6
7 status. However, on his monograph about the archaeology and history of Samnites,
8
9 Tagliamonte (1997) notes that rich burials are most often quantitatively rather than
10
11 qualitatively rich, because the item categories he considered were largely similar to poorer
12
13 burials.
14

15 16 **Determination of age, sex and chronological collocation.** 17

18
19 Only full adult males (as judged by fully closed epiphyses) not showing sign of
20
21 advanced senescence or manifest pathological conditions were included. Sex determination
22
23 was carried by cross-validating various sources of information: a) before collecting other
24
25 information, sex was determined on the basis of pelvic and cranial morphology by taking into
26
27 account diagnostic traits (Acsadi and Nemeskeri, 1970; Buikstra and Ubelaker, 1994;
28
29 Bruzek, 2002); b) the ‘archaeological sex’ of the individual was considered for Orientalizing-
30
31 Archaic burials, which show marked gender-based grave good differences; c) the sex
32
33 determination made in previous studies was taken into account (Parise Badoni and Ruggeri
34
35 Giove, 1980; Piccirilli, 1999; Bestetti, 2002; Ridolfi, 2002; Cosentino et al., 2001; d’Ercole et
36
37 al., 2003a,b; Melandri, 2005); d) we developed discriminant analysis equations based on the
38
39 femoral and humeral supero-inferior head diameters from individuals whom sex was
40
41 reasonably certain and applied them to the rest of the sample (Sparacello, 2013). The
42
43 chronological collocation of each burial was derived from previous studies based on the
44
45 typologies of the grave goods (Parise Badoni and Ruggeri Giove, 1980; Piccirilli, 1999;
46
47 Bestetti, 2002; Ridolfi, 2002; Cosentino et al., 2001; d’Ercole et al., 2003a,b; Melandri, 2005;
48
49 Napolitano, 2012; Sparacello, 2013; Weidig, 2014; d’Ercole, Weidig, unpublished data).
50
51
52
53

54
55 Statistical analysis was conducted using Statistica 10 (Statsoft, 2011). The relationship
56
57 between humeral asymmetry and the continuous variable ‘Status Index’ was explored through
58
59
60

1
2
3 parametric and non-parametric correlations. In order to run ANOVAs, the Status Index was
4
5 categorized in a stepped tier system of increasing status levels through the observation of
6
7 histograms (with 5 points SI increments). The boundaries between SI categories were drawn,
8
9 when possible, based on clear changes in the frequency of burials in the histograms. For
10
11 example, Orientalizing-Archaic burials display a clear drop in frequency for SI above 45
12
13 (details and histograms can be found in Sparacello, 2013). Statistical significance of the
14
15 differences in humeral asymmetry between categorical groups based on the Status Index were
16
17 evaluated via ANOVAs and post-hoc parametric Tukey's Honestly Significant Difference
18
19 tests, as well as pairwise non-parametric Mann-Whitney U-Tests.
20
21

22 RESULTS

23
24
25 Table 2 displays the results of parametric and non-parametric correlation tests between
26
27 the Status Index and humeral bilateral asymmetry. A positive correlation is present only in
28
29 Orientalizing-Archaic, and is highly statistically significant: individuals with higher Status
30
31 Index tend to have higher humeral asymmetry (Pearson's $r=0.244$, $p<0.001$; Spearman's
32
33 $\rho=0.188$, $p<0.01$, Figure 2). When transforming the variables to make them normally
34
35 distributed, the parametric correlation still shows significant results (Log_{10} of the Status Index
36
37 on the square root of humeral bilateral asymmetry: $r=0.22$, $p<0.01$). When excluding 76
38
39 individuals for which the location of the cross section was bilaterally estimated, i.e. when
40
41 length in both sides could not be measured, results remain similar ($N=141$. Pearson's $r=0.247$,
42
43 $p<0.01$; Spearman's $\rho=0.217$, $p<0.01$).
44
45
46

47 Insert Table 2 and Figure 2 about here

48
49 Figure 3 shows the results of an ANOVA for humeral bilateral asymmetry in
50
51 Orientalizing-Archaic males with categorized Status Index as the factor (main effect
52
53 $p<0.001$). Table 3 contains the sample statistics, post-hoc parametric and non-parametric
54
55 pairwise comparisons between status categories. Individuals falling in the higher status
56
57
58
59
60

1
2
3 category are on average more lateralized than the other subsamples (Orientalizing-Archaic
4
5 males with Status Index above 45 have an average humeral bilateral asymmetry of 31.4%,
6
7 while the category with Status Index between 0-15 shows an average humeral bilateral
8
9 asymmetry of 19.85%), and the result is statistically significant ($p < 0.01$ after multiple
10
11 comparisons correction).
12

13
14 Insert Figure 3 and Table 3 about here
15

16 In the Hellenistic period, average male humeral asymmetry for all individuals pooled
17
18 (18.6%) decreases when compared to the Orientalizing-Archaic (24.4%), and the difference is
19
20 highly significant ($p < 0.0001$, Mann-Whitney U-Test). No significant correlation between
21
22 status and male humeral bilateral asymmetry is present (Figure 4, and Table 2). However,
23
24 when dividing the sample in status categories, the ANOVA shows a significant main effect
25
26 ($p < 0.05$), and the 'low status' males (Status Index between 0-60) are significantly more
27
28 lateralized when compared to individuals with Status Index between 60-120 (Figure 5, and
29
30 Table 4).
31
32

33
34 Insert Figure 4, 5 and Table 4 about here
35

36 It should be noted that results remain similar when considering the data deriving from
37
38 the Bazzano necropolis only, which has the highest number of individuals from both periods
39
40 (Table 1). The correlation between Status Index and percent humeral bilateral asymmetry is
41
42 present in the Orientalizing-Archaic period only ($N=72$. Pearson's $r=0.319$, $p < 0.01$;
43
44 Spearman's rho non-significant), and individuals in the highest status category have
45
46 significantly higher asymmetry than the others ($p < 0.001$).
47
48

49 50 **DISCUSSION**

51
52 In this study, we utilized a bioarchaeological research framework with the purpose of
53
54 investigating shifts in military organization and power relationships. This was done by
55
56 integrating behavioral inferences based on acquired skeletal properties (CSG humeral
57
58
59
60

1
2
3 asymmetry) with archaeological information suggestive of the social standing of the
4
5 individual. Both sources of information relied on assumptions whose caveats need to be
6
7 discussed, but results follow the pattern expected on the basis of archaeological and historical
8
9 data.

10
11 On the basis of the model of an elite army, we expected males of the Orientalizing-
12
13 Archaic period to show a correlation between Status Index (as a proxy for social status) and
14
15 humeral bilateral asymmetry in torsional rigidity (as a proxy for frequent weapon use). The
16
17 results confirm the expectation: a positive correlation between status and humeral asymmetry
18
19 is present, and is statistically significant (no correlation is present among females from the
20
21 same period, Sparacello, 2013). When dividing the sample in status categories, individuals
22
23 falling in the highest category show a remarkably higher, statistically significant level of
24
25 asymmetry when compared to the others. The results are similar when considering the
26
27 Bazzano necropolis only, strengthening the interpretation that we are assisting to a real pattern
28
29 within a population.
30
31
32

33
34 We interpret the above pattern as a bioarchaeological confirmation that Samnites of
35
36 the Orientalizing-Archaic period had elite armies. Similarly to the hoplite Greek military
37
38 system, which much influenced Italic culture in the Orientalizing-Archaic period, access to
39
40 military service depended on wealth and aristocratic status (Hammond, 1959; Hanson, 1989;
41
42 Boatwright et al., 2004). The scenario depicted by biomechanical analysis suggests that
43
44 warrior paraphernalia were not only a display of status, but were buried with individuals that,
45
46 since a young age, were destined to a military career and highly trained in the use of the
47
48 Samnite weapons of choice in the Orientalizing-Archaic. This is consistent with the fact that,
49
50 at the time, offensive equipment included exclusively one-handed weapons such as short
51
52 swords, daggers, hatchets, maces, and especially javelins (d'Ercole and Benelli, 2004;
53
54 Weidig, 2014), after which the different Samnite people were called by the Greeks ('saunion'
55
56
57
58
59
60

1
2
3 means 'javelin' in ancient Greek; Tagliamonte, 2009). The same weapons are often present in
4
5 infantile and juvenile graves (Cianfarani et al., 1978; Parise Badoni and Ruggeri Giove, 1980;
6
7 Tagliamonte, personal communication). Conversely, results suggest that lower social strata
8
9 did not normally have access to military activities, and mostly were involved in agricultural
10
11 activities, which does not significantly influence humeral asymmetry (Marchi and Sparacello,
12
13 2006; Sparacello and Marchi, 2008; Sparacello et al., 2011).

16 Although the correlation between humeral asymmetry in torsional rigidity (J) and the
17
18 Status Index is significant, it is rather weak and has a low predictive power. In addition to the
19
20 noise in the model due to individual behavioral variability, and to the inherent error present in
21
22 bioarchaeological methods, variability in the degree of lateralization of the humerus exists
23
24 despite roughly the same amount of training in unimanual activities (Jones et al., 1977;
25
26 Trinkaus et al., 1994; Haapsalo, 2000; Shaw and Stock, 2009). In addition, the Status Index
27
28 was calculated as a continuous value, but social strata were probably only a few. Therefore, it
29
30 would be unrealistic to expect high predictive power in a continuous numerical setting.
31
32 Indeed, when categorizing the Status Index, the expected pattern emerges more clearly and
33
34 results are highly significant.

38 Another reason for the weakness of the correlation between asymmetry in torsional
39
40 rigidity and Status Index in the Orientalizing-Archaic is the possibility that some warriors,
41
42 and thus high-status members of the society, were buried with little grave goods. There is
43
44 ample evidence in literary sources (such as Homer's work) that funerary treatment of warriors
45
46 in Orientalizing-Archaic times depended not only on wealth and aristocracy, but also on
47
48 whether the warrior had a 'good' or 'bad' death (Humphreys, 1980; Langdon, 2005). In case
49
50 of 'bad death', an aristocratic warrior was often buried with a single item, for example a
51
52 bronze razor indicating his adult age and male gender. An example of such treatment was
53
54 identified for the burial 531 of the Fossa necropolis (Cosentino et al., 2001), which
55
56
57
58
59
60

1
2
3 unfortunately was too fragmentary to be included in the study. However, this suggests that a
4
5 directional bias may be present when assessing the status of individuals based on grave good
6
7 richness: some high-status individuals may be erroneously included in the low-status
8
9 category. The opposite is unlikely, i.e. that a low-status individual could have been buried
10
11 with rich grave goods and therefore included in the high-status category. Thus, it is likely that
12
13 the high-status category obtained here is a partial but reasonably non-biased depiction of the
14
15 elite social strata of the Samnite society. The high humeral asymmetry and the virtual absence
16
17 of non-lateralized individuals strongly suggest that unimanual activities – i.e. training in the
18
19 use of weapons – were an important component of their life.
20
21

22
23 It could be questioned whether high humeral asymmetry implies a behavioral
24
25 correlate, and whether weapon training is the sole explanation for asymmetry in this setting.
26
27 Levels of asymmetry like the one observed among high-status Orientalizing-Archaic males
28
29 are several times higher than physiological asymmetry, which is around 8-12%, (Trinkaus et
30
31 al., 1994; Shaw and Stock., 2009). This must be due to frequent, highly stressful unimanual
32
33 activities, as demonstrated by experimental studies (Bass et al., 2002; Ducher et al., 2005;
34
35 Shaw and Stock, 2009). Churchill et al. (1996) and Rhodes and Knüsel (2005) noted that the
36
37 high loading rates and intermittent character of training correspond to the pattern of activities
38
39 that best stimulate osteogenic response (Burr et al., 1996, 2002; Robling et al., 2002).
40
41 Experimental evidence shows that violently swinging the whole arm is the activity that mostly
42
43 generates high levels of torque in humeral mid-distal shaft (Sabick et al., 2004), thus the use
44
45 of mid-distal estimates of torsional rigidity appears appropriate.
46
47
48

49
50 Various activities have been proposed to explain high asymmetry in past populations
51
52 such as hunting via atl-atl (Churchill et al., 1996; 2000; Churchill and Rhodes, 2009), and
53
54 woodworking (Marchi et al., 2006, 2011; Sparacello and Marchi, 2008). Woodworking and
55
56 metallurgy were most likely widespread activities in the Iron Age, and conceivably were the
57
58
59
60

1
2
3 cause of high asymmetry for certain individuals in our samples. However, groups whose
4
5 subsistence was based on agriculture in post-Neolithic times – despite the likely presence of
6
7 blacksmiths and woodcutters in these samples – do not show significantly higher asymmetry
8
9 than modern sedentary people, but only higher average humeral strength (Trinkaus et al.,
10
11 1994; Sparacello and Marchi, 2008; Sparacello et al., 2011). It is probable that, among
12
13 agriculturalists, occupations that generate high and asymmetric loads on the upper limb
14
15 pertain to specialized individuals, rather than being shared, therefore have little influence on a
16
17 sample's mean. On the contrary, high-status Orientalizing-Archaic individuals show a level of
18
19 asymmetry (31.4%) that is significantly higher than trained medieval swordsmen (Sparacello
20
21 et al., 2011), and similar to the one shown by a sample of cricket pitchers who had been
22
23 training since early adolescence (Shaw and Stock 2009). Among bioarchaeological samples,
24
25 only Upper Paleolithic people, whose hunting techniques were based on throwing weapons,
26
27 show higher average levels of asymmetry (Churchill et al., 1996; 2000; Churchill and Rhodes,
28
29 2009). It appears that only the widespread presence and early onset of a highly repetitive and
30
31 stressful unimanual activity can raise the average asymmetry to the levels seen in
32
33 Orientalizing-Archaic high-status males. We believe that the most likely explanation is the
34
35 early onset (pre- and peri- adolescent) and frequent practices of weapon training, given that
36
37 elite social status, wealth and warlike prowess were intertwined in the Orientalizing-Archaic
38
39 period (d'Ercole, 1990; Tagliamonte, 1997, 1999; Cosentino et al., 2001). Early historical
40
41 accounts report that the Italic mountain dwellers of central Abruzzo were 'exceptionally
42
43 strong people' who 'educated their boys in the Spartan manner' and were 'accustomed to the
44
45 use of weapons' and 'defend their settlements with the sturdy right arms of their men rather
46
47 than with walls' (Salmon, 1967; p 30; Tagliamonte, 1994; p 45-46). Accordingly, high
48
49 lateralization is present preferentially in the wealthiest segment of the Orientalizing-Archaic
50
51 population, which is the least likely to be highly infiltrated by blacksmiths and woodcutters.
52
53
54
55
56
57
58
59
60

1
2
3 Finally, the significant decrease in humeral asymmetry in males of the Hellenistic period,
4
5 when weapons disappear from burials but no evidence is available for a decrease in
6
7 metallurgical production or woodworking, further suggests that high asymmetry in the
8
9 Orientalizing-Archaic period was due to weapon training. It should be noted that the pre- and
10
11 peri- adolescent onset of unimanual training that we infer from historical and iconographic
12
13 sources would address one of the problems of CSG bioarchaeological analysis pointed out by
14
15 various authors (Pearson and Lieberman, 2004; Meyer et al., 2011; Jurmain et al., 2012), i.e.
16
17 that activities performed later in life may not result in marked changes in periosteal bone
18
19 geometry.
20
21

22
23 During the Hellenistic period, Samnites deployed large armies against Romans and
24
25 fought a number of pitched battles (Salmon, 1967; Tagliamonte, 1994). Roman historians
26
27 often tended to exaggerate the number of warriors in the enemy's army, either to justify the
28
29 setbacks or to exalt the victories. However, the analysis of historical sources suggests that
30
31 Samnites were able to mobilize thousands of soldiers (Salmon, 1967). These large armies
32
33 were most likely formed by conscripts: the historian Livy reports that at a certain point all the
34
35 able men were forced to 'consecrate their head to Jupiter'. Access to the army was clearly no
36
37 longer exclusive to the elites, but extended on an ethnic and political basis to all the
38
39 population (Tagliamonte, 1997). Thus, the passage to the standing army corresponded to a
40
41 shift in its composition from wealthy elites to individuals drawn from the lower classes
42
43 (Otterbein, 1970; Claessen and Skalnik, 1978).
44
45

46
47 Results of this study support the hypothesis that in Hellenistic times the warring force
48
49 was no longer drawn from the higher social strata. In a context of overall significantly
50
51 decreased asymmetry, no positive correlation between the Status Index and humeral bilateral
52
53 asymmetry is present, and individuals with high status are no longer more lateralized than the
54
55 others. This suggests that the upper limb functional adaptations of elite males were no longer
56
57
58
59
60

1
2
3 influenced by early-onset, frequent weapon training. Indeed, weapons virtually disappear
4
5 from the assemblages of grave goods, and a new emphasis on ornaments and the care of the
6
7 body develops (d'Ercole, 1990; Copersino and d'Ercole, 2003). In contrast, Hellenistic
8
9 individuals in the lowest Status Index category show the highest level of humeral asymmetry.
10
11 This suggests that the lower social strata in Hellenistic times were more likely to include
12
13 individuals that performed stressful unimanual activities – possibly including weapon use –
14
15 than the upper social strata.
16
17

18
19 The positive correlation between status and humeral asymmetry present in the
20
21 Orientalizing-Archaic period is not substituted by a negative correlation. This would be
22
23 expected if a large portion of the lower class was now performing weapon training. We may
24
25 speculate that conscripts were most likely individuals that entered into the army as adults, and
26
27 did not train as much, or as early in life compared to Orientalizing-Archaic aristocratic scions.
28
29 Moreover, although general drafts may have happened, it is likely that only a portion of the
30
31 lower social strata joined the army permanently or intermittently. Most of the people were
32
33 probably involved in agricultural activities that did not influence humeral asymmetry.
34
35 Accordingly, the results show that individuals with low Status Index in Hellenistic times show
36
37 substantial variability in humeral asymmetry, and include also highly lateralized individuals.
38
39

40 41 **CONCLUSIONS**

42
43 We proposed a bioarchaeological research framework jointly analyzing epigenetic
44
45 skeletal properties and funerary treatment information to contribute to the study of ancient
46
47 warfare and military organization. The skeletal proxy for involvement in unimanual armed
48
49 conflict and/or training was high humeral bilateral asymmetry in torsional rigidity. As a proxy
50
51 for the social standing of the individual, we used the Status Index based on the presence of
52
53 grave good categories and the number of funerary items. Results are compatible with the
54
55 model expected from archaeological, iconographic, and historical evidence. We expected that
56
57
58
59
60

1
2
3 Orientalizing-Archaic Samnites had an elite militia, where the cadets were the scion of the
4
5 wealthier social strata. Accordingly, humeral asymmetry and Status Index are positively
6
7 correlated, and the subsample of individual with the richest grave goods shows significantly
8
9 higher asymmetry. We expected that Hellenistic Samnites developed a conscript or standing
10
11 army, where the bulk of the warring force was drawn from the lower social strata.
12
13 Accordingly, we found no correlation between Status Index and humeral asymmetry, and the
14
15 subsample of individuals with fewer grave goods was the most lateralized.
16
17

18
19 We believe that, thanks to the employment of a large sample narrowed in a small
20
21 temporal and geographical scale, the proposed research framework was able to detect a shift
22
23 in military organization that happened among Samnites in concomitance with the passage to
24
25 the state. Results of this study support the use of CSG analysis, when cautiously interpreted
26
27 and framed in a strong bioarchaeological theoretical framework, to investigate past
28
29 sociopolitical development, changes in power relationships, and warfare.
30
31

32 **Acknowledgments**

33
34 Our gratitude goes to Osbjorn Pearson, Brigitte Holt, Lawrence Straus, and James
35
36 Boone for mentoring and guidance during the completion of the research. Thanks to Joachim
37
38 Weidig, Gianluca Tagliamonte, Sara Napolitano, and Andrea D'Andrea for archaeological
39
40 counseling on Samnite's burial practices. Thanks to Colin Shaw for sharing his PQCT data of
41
42 modern humeri. Thanks to the Soprintendenza Archeologica d'Abruzzo for allowing the study
43
44 of the material and to Andrea Pessina, Silvano Agostini, Vincenzo Torrieri, Domenico
45
46 Mancinelli, Alberta Martellone, and Paolo Eusani for assistance during data collection. The
47
48 staff of the Musè of Celano and in particular the curator Stefania Montanaro gave invaluable
49
50 help and support during the data collection. Thanks to Sergio Tassoni e Fabrizio Tennina for
51
52 logistical assistance during data collection and to Damiano Marchi, Charlotte Roberts, and
53

Pelutium	-	4
Poggio Picenze - Varranone	5	1
San Pio - Campo Rosso	5	-
San Pio - Colli Bianchi	22	7
Total	217	144

Table 1 – Number of male individuals included in this study, by necropolis and period.

	N	Pearson's R	P-value	Spearman's R	P-value
Orientalizing-Archaic Males	217	0.244	P<0.0001	0.188	<0.001
Hellenistic Males	144	- 0.096	NS	- 0.064	NS

Table 2 – Pearson's parametric correlation and Spearman's non-parametric correlation between Status Index and percent humeral bilateral asymmetry in Orientalizing-Archaic and Hellenistic individuals. NS, statistically non-significant.

Orientalizing-Archaic Males	HUMBA			Pairwise Comparisons ¹	
	N	Mean	SD	Status Index 15-45	Status Index M 45>
Status Index 0-15	34	19.85%	13.57	NS	** (**)
Status Index 15-45	137	23.22%	14.14		** (**)
Status Index 45>	46	31.40%	17.09		
All	220	24.37%	15.06		

Table 3 – Comparison of percent humeral bilateral asymmetry among Orientalizing-Archaic male subsamples based on status categories.

¹ Post-hoc comparisons of an ANOVA with status categories as factor. Tukey's Honestly Significant Difference is provided outside of parentheses; pairwise non-parametric Mann-Whitney U-Test is provided in parentheses. Statistical significance level: NS, non-significant; *, $p < 0.05$; **, $p < 0.01$.

Hellenistic Males Status Index	HUMBA			Pairwise Comparisons ¹		
	N	Mean	SD	60-120	120-180	180>
0-60	42	22.77%	15.37	* (*)	NS	NS
60-120	46	15.42%	10.30		NS	NS
120-180	34	19.37%	11.78			NS
180>	22	17.03%	11.72			
All	146	18.61%	12.72			

Table 4 – Comparison of percent humeral bilateral asymmetry among Hellenistic male subsamples based on status categories .

¹ Post-hoc comparisons of an ANOVA with status categories as factor. Tukey's Honestly Significant Difference is provided outside of parentheses; pairwise non-parametric Mann-Whitney U-Test is provided in parentheses. Statistical significance level: NS, non-significant; *, p<0.05; **, p<0.01.
