Introduction.—In the last few years, imaging atmospheric Cherenkov telescopes have been used to search for dark matter (DM) signals in very-high-energy (VHE; $E_\gamma > 100$ GeV) $\gamma$ rays [1–10]. Objects with large predicted DM density, like the Galactic center (GC), the central Galactic halo region (CGH), dwarf galaxies, or centers of nearby galaxies were studied. All such searches concentrated on the detection of $\gamma$ rays produced in decays of secondary particles—mostly neutral mesons—in the process of DM self-annihilation or decay (see, e.g., Refs. [11,12]). The broad energy distribution of such $\gamma$ rays is continuous and therefore more difficult to distinguish from $\gamma$-ray emission from astrophysical (particle accelerating) sources, as opposed to spectral features, which would pose a much more striking evidence for a DM-induced $\gamma$-ray signal. The most prominent spectral feature is a $\gamma$-ray line (note, however, that VHE $\gamma$-ray line emission, flux limits of $(2 \times 10^{-7} - 2 \times 10^{-5}) \text{ m}^{-2} \text{s}^{-1} \text{sr}^{-1}$ and $(1 \times 10^{-8} - 2 \times 10^{-6}) \text{ m}^{-2} \text{s}^{-1} \text{sr}^{-1}$ are obtained for the central part of the Milky Way halo and extragalactic observations, respectively. For a DM particle mass of 1 TeV, limits on the velocity-averaged DM annihilation cross section reach $(3 \times 10^{-37}) \text{ cm}^{3} \text{s}^{-1}$, based on the Einasto parametrization of the Galactic DM halo density profile.

extragalactic sky covered by H.E.S.S. observations, with regions containing known VHE γ-ray sources being excluded from the analysis. For both data sets, the uncertainty on the strength of a putative DM annihilation signal is much reduced in comparison to the observations of centers of galaxies: for the CGH, the very center is not considered, thus avoiding a region where the DM profile is only poorly constrained [8]. For the extragalactic data set, differences in DM density between individual substructures are averaged out by observing many different fields of view [19]. One should note, however, that a potentially large (but highly uncertain) γ-ray flux from Galactic DM annihilations may contribute to the extragalactic analysis [20].

Methodology and results.—The CGH data set is composed of 112 h (live time) of GC observations recorded with the H.E.S.S. VHE γ-ray instrument (see Ref. [21] and references therein) during the years 2004–2008. (Data from later periods were excluded, because the gradual degradation in time of the optical efficiency of the instrument would result in an increased energy threshold.) The mean distance between the telescope pointing positions and the GC is 0.7°, with a maximum of 1.5° [8]. The extragalactic data set comprises 1153 h of H.E.S.S. observations taken during 2004–2007, targeted at various extragalactic objects. Regions in the field-of-view (FOV) containing known VHE γ-ray sources are excluded by masking out a circular region (of radius 0.2° for point sources) around the source position.

Observations with zenith angles larger than 30° are excluded from the analysis to lower the energy threshold, resulting in a mean zenith angle of 14° (19°) for the CGH (extragalactic) observations. Only γ-ray-like events are accepted for which the distance between the reconstructed γ-ray direction and the observation direction of the H.E.S.S. array is smaller than 2°, avoiding showers being reconstructed too close to the edges of the ~5° diameter FOV of the H.E.S.S. cameras [21]. Furthermore, events are considered only if they pass H.E.S.S. standard γ-ray selection criteria defined in Ref. [21] and triggered all four telescopes. Only 15% of the total event sample is kept by the latter selection. However, compared to the H.E.S.S. standard analysis, such selection leads to a better signal to background ratio and an improved energy resolution of Gaussian width σ_E (17% at 500 GeV and 11% at 10 TeV), and therefore increases the sensitivity of the analysis to spectral features by up to 50%. The energy threshold is 310 GeV (500 GeV) for the CGH (the extragalactic) data set.

Differential flux spectra are calculated from the reconstructed event energies separately for the CGH and extragalactic data sets using zenith angle-, energy- and offset-dependent effective collection areas from γ-ray simulations. Because sky regions containing known VHE γ-ray sources were excluded from the analysis, the spectra consist mostly of γ-ray-like cosmic-ray background events (and a fraction of ~10% of electrons). These spectra are well described by the empirical parametrization

\[
\frac{dN}{dE} = a_0 \left( \frac{E}{1\text{ TeV}} \right)^{-2.7} \left[ P(x) + \beta G(x) \right],
\]

where \( E_\gamma \) is the reconstructed energy of the event under γ-ray hypothesis and \( P(x) = \exp(a_1 x + a_2 x^2 + a_3 x^3) \). \( G(x) \) is a Gaussian function with mean \( \mu_x \) and rms \( \sigma_x \), and \( x = \log_{10}(E_\gamma/1 \text{ TeV}) \). The free parameters \( a_{0,3}, \beta, \mu_x, \) and \( \sigma_x \) are optimized simultaneously by a maximum likelihood approach based on the binned event count spectrum. Because the number of reconstructed counts \( n_i \) in energy bin \( i \) of the count spectrum is Poisson distributed, the log-likelihood function takes the form

\[
\ln L = \sum_{i=1}^{N} n_i \ln \lambda_i - \lambda_i,
\]

where \( \lambda_i \) is the number of counts in bin \( i \) that is expected according to the flux spectrum parametrization given in Eq. (1), and \( N \) is the total number of bins of the count spectrum. As an example, Fig. 1 shows the differential flux spectrum and the best-fit background parametrization obtained for the CGH data set.

![Fig. 1](color online). Reconstructed flux spectrum of the CGH region, using 25 equidistant bins per unit of \( \log_{10}(E_\gamma) \). Flux points have been multiplied by \( E_\gamma^{3.7} \). The data consist mostly of hadronic cosmic-ray background events, reconstructed using a γ-ray hypothesis. The spectrum is well described by the parametrization introduced in Eq. (1), depicted by the black solid line. The corresponding χ²-test probability is \( p = 0.34 \). The two contributions \( P(x) \) and \( G(x) \) are shown by the dashed-dotted and the dashed curve, respectively. Note that the shape of the Gaussian function \( G(x) \) is much broader than the expected monochromatic line feature from DM annihilations. As an example, the red curve (denoted “simulated line” in the legend) shows the expected signal of a line at \( E_\gamma = 2 \text{ TeV} \) that would be detected with a statistical significance of 5 standard deviations above the background.
On top of the smooth cosmic-ray flux spectrum, a monochromatic $\gamma$-ray line may be identified as a Gaussian peak of width $\sigma_E$ centered at the line energy $E_\gamma$. (In this context, the term monochromatic line refers to spectral features with energy width much smaller than the energy resolution $\sigma_E$ of the H.E.S.S. instrument.) To search for such lines, a Gaussian term with fixed energy $E_\gamma$ and fixed corresponding width $\sigma_E$ was added to the spectrum parametrization given in Eq. (1). The spectrum was re-fit, and from the normalization of the Gaussian the flux of the putative line was reconstructed. By repeating this procedure, using ten logarithmically equidistant energies $E_\gamma$ per decade of energy, the flux spectrum was scanned for monochromatic $\gamma$-ray signatures. Line scans were performed in the energy range 0.5–20 TeV and 0.8–25 TeV for the CGH and the extragalactic data sets, respectively.

No $\gamma$-ray line flux was found to exceed the a priori chosen detection threshold of $\Delta \ln L = 12.5$, corresponding to a significance of 5 standard deviations above the background level for Gaussian parameters. Thus flux upper limits were calculated by constraining the flux normalization of the Gaussian to be non-negative in the fit and using the MINOS package from the MINUIT [22] fitting tool to calculate asymmetric errors with error level $\Delta \ln L = 1.35$, corresponding to a 95% C.L. one-sided limit on the flux of the line [15,23]. These limits are shown in Fig. 2. To test whether the limits are compatible with random fluctuations of the background, a large number of statistically randomized fake background spectra were simulated using the best-fit background parametrization as an input, and limits were obtained for each of these spectra. The resulting mean limits, together with the 68% C.L. region calculated from the limit distribution at each test energy, are shown in Fig. 2 for comparison. Also shown are mean reconstructed fluxes from simulated lines that are detected with a significance of 5 standard deviations using the above prescription.

Additionally, flux upper limits were determined for broader spectral features like those arising due to internal bremsstrahlung (IB). As an example, calculations by Ref. [14] in the framework of supersymmetric models predict the contribution of IB photons to the $\gamma$-ray spectrum to dominate over secondary $\gamma$-ray production for photon energies close to the DM (neutralino) mass $m_\chi$. Flux upper limits for the benchmark models BM2 and BM4 of Ref. [14] were calculated following the technique described above. First, the signal shapes predicted by the models were convolved with the energy response of the instrument. Together with the background parametrization, the resulting templates were then fitted (with the normalization of the template and the background parameters being free variables in the fit) to the flux spectrum. Note that only the IB part of the full annihilation spectra of these models is considered because the contribution from production of secondary photons steeply decreases toward $m_\gamma$ (see Ref. [14]), and is therefore hard to discriminate against the cosmic-ray background. In any case, because these models were calculated for a very specific set of minimal supersymmetric standard model parameters (and hence neutralino mass), they can only serve as a template to demonstrate the sensitivity of H.E.S.S. for features of similar shape (and are therefore referred to as BM2-like and BM4-like limits). Figure 3 shows that—because of the intrinsic widths of the expected features—these limits are typically weaker by a factor of 2 (BM2-like) to 10 (BM4-like) compared to the monochromatic line limits. Note that all flux limits do also constrain putative features in the spectrum of cosmic-ray electrons and positrons, because the H.E.S.S. experiment exhibits a similar sensitivity for detecting these particles as for $\gamma$ rays.

Possible systematic uncertainties due to the unknown shape of the background spectrum have been extensively studied, e.g., by changing the background parametrization described in Eq. (1) to one based on Legendre polynomials. The background parametrization does not show any significant correlation with shape parameters of spectral signatures, in particular with regard to the $G(x)$ term. The stability of the $\gamma$-ray flux reconstruction was investigated by adding artificial peaks to the background spectrum and reconstructing them with the fitting procedure described above. The systematic uncertainty on the reconstructed peak flux was of the order of a few percent, and the fit of the background was found to be very stable and independent of the location and normalization of the artificial peak. On the other hand, despite detailed Monte Carlo simulations of the instrument, the true energy resolution $\sigma_E$ of the instrument might be underestimated. When $\sigma_E$ is
FIG. 3 (color online). Flux upper limits on spectral features arising from the emission of a hard photon in the DM annihilation process. Limits are exemplary shown for features of comparable shape to those arising in the models BM2 and BM4 given in Ref. [14]. The monochromatic line limits, assuming $m_\chi = E_\gamma$, are shown for comparison.

artificially enlarged by, e.g., 20%—i.e., $\sigma_E = 20\% (13\%)$ at $E_\gamma = 500$ GeV (10 TeV)—upper limits get shifted to larger values by about 15%–20%, depending on the energy and the statistics in the individual spectrum bins. The maximum shift is observed in the extragalactic limit curve and amounts to 40%. In total, the systematic error on the flux upper limits is estimated to be about 50%. All flux upper limits were cross-checked using an alternative analysis framework [24], with an independent calibration of camera pixel amplitudes, and a different event reconstruction and event selection method, leading to results well consistent within the quoted systematic error.

For the Einasto parametrization of the DM density distribution in the Galactic halo [20], limits on the velocity-weighted DM annihilation cross section into $\gamma$ rays, $\langle \sigma v \rangle_{\chi\chi\rightarrow\gamma\gamma}$, are calculated from the CGH flux limits using the astrophysical factors given in Ref. [8]. The result is shown in Fig. 4 and compared to recent results obtained at GeV energies with the Fermi-LAT instrument.

Summary and conclusions.—For the first time, a search for spectral $\gamma$-ray signatures at very-high energies was performed based on H.E.S.S. observations of the central Milky Way halo region and extragalactic sky. Both regions of interest exhibit a reduced dependency of the putative DM annihilation flux on the actual DM density profile. Upper limits on monochromatic $\gamma$-ray line signatures were determined for the first time for energies between $\sim 500$ GeV and $\sim 25$ TeV, covering an important region of the mass range of particle DM. Additionally, limits were obtained on spectral signatures arising from internal bremsstrahlung processes, as predicted by the models BM2 and BM4 of Ref. [14]. It should be stressed that the latter results are valid for all spectral signatures of comparable shape. Besides, all limits also apply for potential signatures in the spectrum of cosmic-ray electrons and positrons.

Flux limits on monochromatic line emission from the central Milky Way halo were used to calculate upper limits on $\langle \sigma v \rangle_{\chi\chi\rightarrow\gamma\gamma}$. Limits are obtained in a neutralino mass range that is complementary to the line searches performed by Fermi-LAT [15], reaching $\sim 10^{-27}$ cm$^3$ s$^{-1}$ at a DM mass of 1 TeV, comparable to those obtained by Fermi-LAT at energies of $\sim 100$ GeV.
