22

23 **Abstract:**

24 Timing of the opening of the Meso-Tethys Ocean, represented by the Bangong–
25 Nuijiang Suture Zone on the Tibetan Plateau, remains controversial. Further research
26 is required to understand the breakup of the northern Gondwana margin and the
27 tectonic evolution of the Tethyan realm. In this study, we present petrography, U–Pb
28 dating and Hf isotopic data for detrital zircons from Upper Carboniferous–Upper
29 Permian strata in the South Qiangtang Terrane on the Tibetan Plateau. These data,
30 together with data from previous literature, indicate a youngest detrital zircon age
31 peak of ca. 550 Ma for Upper Carboniferous–Lower Permian strata. This is far older
32 than the depositional age of ca. 300 Ma and indicates a source in the stable Gondwana
33 Continent. Upper Permian strata yield younger ages (490–247 Ma) with peaks at ca.
34 460, 355, 290 and 260 Ma, indicating a source in the active South Qiangtang Terrane.
35 Combined with the unconformity between the Lower and Upper Permian strata in the
36 western South Qiangtang Terrane, we conclude that a significant change in
37 sedimentary provenance occurred at 280–260 Ma. This provenance change might
38 have resulted from the 300–279 Ma rifting magmatism on the northern Indian margin
39 of Gondwana (e.g., South Qiangtang). The 300–279 Ma magmatism is interpreted to
40 reflect the early stages of rifting, and the subsequent 280–260 Ma sedimentary
41 provenance change is interpreted as the later stage, both of which established a
42 complete Early–Middle Permian (300–260 Ma) rifting process that marks the opening
43 of the Meso-Tethys Ocean.

44 **Key words:** Detrital zircon; Rifting; Indian margin of Gondwana

45 **1. Introduction**

46 The Meso-Tethys Ocean, which is represented by the Bangong–Nujiang Suture
47 Zone (BNSZ) on the central Tibetan Plateau, places important constraints on the
48 Mesozoic tectonic history of the Tibetan Plateau (Kapp et al., 2007; Fan et al., 2012;
49 Zhang et al., 2014; Zhu et al., 2016), and provides insights into widespread late
50 Mesozoic mineralization within central Tibet (Geng et al., 2016; Li et al., 2018).
51 Although the BNSZ has been studied extensively (Allègre et al., 1984; Yin and
52 Harrison., 2000; Kapp et al., 2007; Shi et al., 2008; Pan et al., 2012; Zhang et al.,
53 2014, 2017, 2019; Li et al., 2014, 2018, 2019, 2020; Zhu et al., 2016; Wang et al.,
54 2016; Zeng et al., 2016; Hu et al., 2017; Liu et al., 2017; Chen et al., 2017; Ma et al.,
55 2017; Fan et al., 2018, 2020; Wu et al., 2018; Hao et al., 2019; Tang et al., 2020; Luo
56 et al., 2020), many aspects of the evolution of the Meso-Tethys Ocean remain
57 controversial, and the timing of the opening of the Meso-Tethys Ocean has been
58 subject to fierce debate (Metcalf, 2013; Zhai et al., 2013; Liao et al., 2015; Chen et
59 al., 2017; Liu et al., 2017; Fan et al., 2017; Wang et al., 2019; Zhang et al., 2019; Li et
60 al., 2019).

61 An understanding of the timing of opening of the Meso-Tethys Ocean is critical
62 for constraining the history of the breakup of the northern Gondwana margin, and for
63 understanding the tectonic evolution of the Tethyan realm. The opening of the
64 Meso-Tethys Ocean is associated with Carboniferous–Permian rifting of the South
65 Qiangtang Terrane from the Indian margin of Gondwana (Metcalf, 2013; Zhai et al.,
66 2013; Liao et al., 2015; Chen et al., 2017; Liu et al., 2017; Fan et al., 2017; Wang et

67 al., 2019; Zhang et al., 2019; Li et al., 2019); therefore, the Carboniferous–Permian
68 strata in the South Qiangtang Terrane (Fig. 1b) are expected to provide crucial
69 information on the timing of the Meso-Tethys opening.

70 In this paper, in order to discuss the timing of the Meso-Tethys opening, we
71 examine the Upper Carboniferous–Upper Permian strata (Fig. 1b) in the South
72 Qiangtang Terrane by using a combined approach of detailed petrographic analysis,
73 detrital zircon U–Pb dating, and Hf isotope analysis. The resultant data allow us to
74 identify a significant change in sedimentary provenance during 280–260 Ma in the
75 South Qiangtang Terrane, which is interpreted as the sedimentary and tectonic
76 response to continental rifting, the precursory process of the Meso-Tethys Ocean
77 opening. This work thus establishes an important framework for the timing of opening
78 of the Meso-Tethys Ocean.

80 **2. Upper Carboniferous–Upper Permian strata in the South**

81 **Qiangtang Terrane**

82 From south to north, the Tibetan Plateau is made up of the Himalaya, Lhasa,
83 South Qiangtang, North Qiangtang, Songpan-Ganzi-Hoh Xil and Qaidam terranes
84 (Fig. 1a). These terranes are separated by five suture zones (Fig. 1a; Allègre et al.
85 1984; Yin and Harrison, 2000; Pan et al. 2012; Metcalfe, 2013; Zhu et al., 2013; Xu et
86 al., 2015; Zhai et al., 2016). This study focuses on the Jiaco and Ritu areas in the
87 middle and western South Qiangtang Terrane, respectively (Fig. 1b), where Upper
88 Carboniferous–Upper Permian strata are widely distributed within complex
89 sedimentary sequences (Figs 1c, 1d, 2).

90 The Upper Carboniferous–Upper Permian strata in the Jiaco area include the
91 Zhanjin, Qudi, Lugu and Jipuria formations (Figs 1c, 2), and those in the Bitu area
92 include the Zhanjin, Qudi, Tunlonggongba, Longge and Jipuria formations (Figs
93 1d, 2).

94 The Zhanjin Formation is dominated by grey–green glacial marine diamictite
95 (Fig. 3a)—formed by the Late Carboniferous–Early Permian Gondwanan glaciation
96 (Jin et al., 2002; Fielding et al., 2008; Zhang et al., 2013; Fan et al., 2015)—sandstone,
97 siltstone and shale. Sakmarian bivalves (e.g., *Eurydema perversum*) and solitary
98 corals (e.g., *Cyathaxonia* and *Lophophyllidium*; Liang et al., 1983; Liu and Cui, 1983;
99 Zhang et al., 2013) in the sandstone and siltstone also indicate a Late Carboniferous–
100 Early Permian age. Slump structures, convolute bedding and Bouma sequences are
101 common in the Zhanjin Formation, indicating a bathyal to abyssal depositional
102 environment (Fan et al., 2015; Zhang et al., 2019). The overlying Qudi Formation is
103 dominated by littoral–neritic sandstone in the western South Qiangtang Terrane, and
104 bathyal to abyssal siltstone and shale in the middle South Qiangtang Terrane (Zhang
105 et al., 2012a, 2019). This Formation contains fusulines (e.g., *Pseudofusulina*,
106 *Chalaroschwagerina*, *Pamirina*) of Early Permian age (Zhang et al., 2012a, 2013).
107 The Lugu Formation in the middle South Qiangtang Terrane is dominated by basalt
108 and littoral–neritic limestone; Early Permian fusulines (*Cancellina*, *Parafusulina*
109 and *Pseudodoliolina*) occur in the basal strata, and Middle Permian
110 *Neoschwagerina* and *Verbeekina* occur in the upper strata of the formation (Nie
111 and Song, 1983a; Zhang et al., 2012a, 2013, 2019). The Tunlonggongba and

112 Longge formations in the western South Qiangtang Terrane are both dominated by
113 littoral–neritic limestone. The Tunlonggongba Formation contains the fusuline
114 *Monodiexodina*, indicating a late Early Permian age (Nie and Song, 1983b). The
115 Longge Formation contains the coral *Iranophyllum*, and the fusulines
116 *Neoschwagerina*, *Dunbarula*, *Sumatrina*, *Chusenella* and *Kahlerina* of late Middle
117 Permian age (Liang et al., 1983; Nie and Song, 1983c; Zhang et al., 2013). The nature
118 of the stratigraphic contact between the Tunlonggongba and Longge formations is
119 unclear, because the Longge Formation occurs as ‘blocks’ in the western South
120 Qiangtang Terrane (Zhang et al., 2019). The Jipuria Formation is dominated by
121 littoral–neritic conglomerate, sandstone, siltstone and limestone, with minor andesite
122 and tuff (Figs 2, 3b; Liang et al., 1983; Xia and Liu., 1997; Mou et al., 2010; Zhang et
123 al., 2013, 2019). This formation overlies the Tunlonggongba Formation with angular
124 unconformity in the western South Qiangtang Terrane, whereas it overlies the
125 Lugu Formation with parallel unconformity in the central South Qiangtang Terrane
126 (Fig. 2). In the western South Qiangtang Terrane, the Jipuria Formation contains
127 the fusulines *Codonotusella*, *Reichelina* and *Palaeofusulina*, the corals
128 *Waagenophyllum* and *Lophophyllidium*, and the brachiopods *Permophricodothyris*
129 and *Leptodus*, all indicating a Late Permian age (Wu and Lan, 1990; Zhang et al.,
130 2013). Due to an absence of fossils, the age of the Jipuria Formation in the middle
131 South Qiangtang Terrane remains unconstrained.

132

133 3. Analytical methods

134 3.1 Sandstone petrographic analysis

135 Sandstone samples from the Upper Carboniferous–Lower Permian Zhanjin
136 Formation and the Upper Permian Jipuria Formation in the South Qiangtang Terrane
137 were prepared and studied using petrographic analysis. Modal analysis was carried out
138 on Upper Permian samples that exhibit minor metamorphism. Approximately 300
139 grains were identified and counted in each sample, following the Gazzi-Dickinson
140 method (Dickinson, 1985); crystals or grains larger than $\sim 60\ \mu\text{m}$ in diameter
141 within rock fragments were counted as single minerals (Ingersoll et al., 1984). The
142 results are presented in Supplementary Table S1.

144 3.2 Zircon U–Pb dating

145 Based on field work, four sandstone samples were selected for U–Pb dating: one
146 from the Upper Carboniferous–Lower Permian Zhanjin Formation in the Jiaco area
147 (sampled S19T21, $33^{\circ}31'31''\text{N}$, $83^{\circ}13'16''\text{E}$, 5323 m elevation), two from the Upper
148 Permian Jipuria Formation in the Jiaco area (sampled D18T16, $33^{\circ}13'40''\text{N}$,
149 $83^{\circ}9'17''\text{E}$, 4926 m elevation; and D18T17, $33^{\circ}8'24''\text{N}$, $83^{\circ}17'49''\text{E}$, 4622 m
150 elevation), and one from the Upper Permian Jipuria Formation in the Ritu area
151 (sampled B19T17, $33^{\circ}34'35''\text{N}$, $80^{\circ}18'4''\text{E}$, 4482 m elevation).

152 Zircon grains were extracted from sandstone samples by crushing and using a
153 combined method of heavy liquid and magnetic separation in the Laboratory of the
154 Geological Team of Hebei Province, Langfang, China. Internal structures of the grains

155 were imaged using cathodoluminescence (CL) in the Continental Dynamics
156 Laboratory, Chinese Academy of Geological Sciences, Beijing, China to select spots
157 for laser ablation–inductively coupled plasma–mass spectroscopy (LA–ICP–MS)
158 analysis. The LA–ICP–MS U–Pb zircon dating was carried out in the Key Laboratory
159 of Mineral Resources Evaluation in Northeast Asia, Ministry of Natural Resources of
160 China, Changchun, China. The spot size was 32 μm for each sample. Helium was
161 used as a carrier gas. The reference zircon standards 91500 (Wiedenbeck et al., 1995)
162 and NIST610 (^{29}Si) were used for instrumental calibration. The Pb correction method
163 of Anderson (2002) was applied, with analytical details following those described by
164 Yuan et al. (2004). Reported uncertainties for the age analyses are given as 1σ values
165 with weighted mean ages at the 95% confidence level. Isotopic data were processed
166 using the GLITTER (version 4.4) and Isoplot/Ex (version 3.0) programs (Ludwig,
167 2003). Reported ages are $^{206}\text{Pb}/^{238}\text{U}$ ages for grains <1000 Ma and $^{207}\text{Pb}/^{206}\text{Pb}$ ages for
168 grains >1000 Ma. For statistical purposes, zircon ages with <10% discordance are
169 used in our discussion.

170

171 3.3 *In situ* zircon Hf isotope analysis

172 Twelve zircons from the Upper Permian sandstone samples (D18T16, D18T17,
173 and B19T17) were analyzed for Hf isotopic compositions. The same dating spots
174 were used for Hf analysis. The Hf isotope data were collected using a NEPTUNE Plus
175 multi-collector (MC)–ICP–MS at the Beijing Createch Testing Technology Co., Ltd,
176 Beijing, China. A single spot ablation mode with a spot size of 44 μm was used to

177 acquire the data. Each measurement consisted of 20 s of background signal
178 acquisition followed by 50 s of ablation signal acquisition, with analytical processes
179 following those described by [Hu et al. \(2012\)](#). Off-line selection, signals integration
180 of analyte, and mass bias calibrations were performed using the ICP-MS DataCal
181 program ([Liu et al., 2010](#)). The analyzed $^{176}\text{Hf}/^{177}\text{Hf}$ ratios for the zircon standard
182 (91500) were 0.282299 ± 31 ($2\sigma_n$, $n=40$), which are in agreement with the
183 recommended value within error ($^{176}\text{Hf}/^{177}\text{Hf}$ ratios of 0.282303 ± 8 at 2σ ; [Goolaerts](#)
184 [et al., 2004](#); [Woodhead et al., 2004](#)).

185

186 **4. Results**

187 **4.1 Sandstone petrography**

188 Sandstone samples from the Upper Carboniferous–Lower Permian Zhanjin
189 Formation in the Jiaco area have undergone lower greenschist facies
190 metamorphism, causing alteration of the muddy matrix into sericite ([Fig. 3c](#)). The
191 samples are dominated by quartz grains (>95%; [Fig. 3c](#)). However, sandstone
192 samples from the Upper Permian Jipuria Formation in the Jiaco area are dominated by
193 poorly sorted quartz grains (76%–83%) and lithic fragments (12%–21%; [Table S1](#)).
194 The lithic fragments comprise mainly limestone and basalt ([Figs 3d–e](#)).

195 Sandstone samples from the Upper Permian Jipuria Formation in the Ritu
196 area are dominated by fine-grained (<0.1 mm) quartz grains (77%–83%),
197 feldspar (8%–12%) and lithic fragments (9%–14%; [Table S1, Fig. 3f](#)).

198 Polysynthetic twinning is common in the feldspar ([Fig. 3f](#)), and lithic fragments

199 composed predominantly of metamorphic and volcanic detritus (Table S1).

200

201 **4.2 Zircon U–Pb dating**

202 Representative cathodoluminescence (CL) images of detrital zircons are
203 presented in Figure S1, and age data are presented in Tables S2–S4.

204 Detrital zircon ages from one Upper Carboniferous–Lower Permian sandstone
205 sample from the Zhanjin Formation from the Jiaco area (S19T21; Fig. 1c) range from
206 3944 to 498 Ma, with two main peaks at ca. 958 and ca. 530 Ma (Fig. 4c). These age
207 distributions are in good agreement with those of detrital zircons from Carboniferous–
208 Lower Permian strata in other areas of the South Qiangtang Terrane (Figs 4d–e).

209 Detrital zircon ages from two Upper Permian sandstone samples from the Jipuria
210 Formation from the Jiaco area (Fig. 1c) yield a similar range of ages from 3630 to 247
211 Ma, with five main peaks at ca. 945, 528, 463, 350, and 260 Ma (Fig. 4b). Detrital
212 zircon ages from one Upper Permian sandstone sample from the Jipuria Formation in
213 the Ritu area (B19T17; Fig. 1d) range from 2664 Ma to 247 Ma, with five main peaks
214 at ca. 1870, 456, 363, 290, and 256 Ma (Fig. 4a). These age distributions are
215 significantly different from those of the Carboniferous–Lower Permian strata in the
216 South Qiangtang Terrane (Fig. 4).

217

218 **4.3 Zircon Hf isotope data**

219 Zircon Hf isotope data are presented in Table S5. Detrital zircons with ages of
220 285–248 Ma from the Upper Permian sandstone samples from the Jipuria Formation

221 have $\varepsilon_{\text{Hf}}(t)$ values of -15.1 to $+12.5$, with T_{DM2} ages (two-stage Hf model ages) in
222 the range of 489–2241 Ma (Fig. 5).

223

224 5. Discussion

225 5.1 Age of the Jipuria Formation in the South Qiangtang Terrane

226 The age of the Jipuria Formation in the Jiaco area of the middle South
227 Qiangtang Terrane is currently unconstrained, owing to a lack of fossils. Andesite
228 and pyroclastic rocks in the Jipuria Formation indicate magmatic eruptions occurred
229 during deposition of the formation (Liang et al., 1983; Xia and Liu., 1997; Mou et al.,
230 2010; Fig. 2); therefore, the depositional age of the Jipuria Formation should be close
231 to the youngest zircon age (Malusa et al., 2011; Cawood et al., 2012; von Eynatten
232 and Dunkl, 2012). To reasonably constrain the depositional age of the Jipuria
233 Formation, we used the mean age of the youngest three or more grains that overlap in
234 age at 2σ (YC 2σ). This method has proved effective in sandstones from the Colorado
235 Plateau (Dickinson and Gehrels, 2009). In the Jiaco area, sandstone samples from the
236 Jipuria Formation yield Late Permian YC 2σ ages of 259 ± 11 Ma ($n = 5$) and 257 ± 11
237 Ma ($n = 5$), which are similar to those of the Jipuria Formation in the Ritu area (YC 2σ
238 = 255 ± 8 Ma, $n = 10$; Fig. S2). These YC 2σ ages (259–255 Ma), together with Late
239 Permian fossils reported in the Ritu area (Wu and Lan, 1990; Zhang et al., 2013),
240 provide strong evidence that the Jipuria Formation in the South Qiangtang Terrane is
241 of Upper Permian age.

242

243 **5.2 Provenance analysis: A 280–260 Ma sedimentary provenance change in the**
244 **South Qiangtang Terrane**

245 Prior to provenance analysis, it is necessary to consider the paleoposition of the
246 South Qiangtang Terrane during the Carboniferous–Permian. The glacial marine
247 diamictites (Fig. 3a) that formed as a result of the Late Carboniferous–Early Permian
248 Gondwanan glaciation (ca. 300 Ma; Jin et al., 2002; Fielding et al., 2008; Zhang et al.,
249 2013; Fan et al., 2015) are widespread in the South Qiangtang Terrane (Fan et al.,
250 2015). This indicates that the South Qiangtang Terrane was located near the
251 Gondwana Continent during the Late Carboniferous–Early Permian period. The
252 distinctive ca. 950 Ma age peak observed in the Carboniferous–Lower Permian strata
253 (Fig. 4) in the South Qiangtang Terrane is consistent with the emplacement of the
254 990–900 Ma granitoids of the Indian margin of Gondwana (Zhu et al., 2013). These
255 observations, together with the similarities between the Early Permian fossils (Zhang
256 et al., 2012a, b, 2013, 2014) and magmatic activity (e.g., the 300–260 Ma mafic
257 magmatism; Zhai et al., 2013; Wang et al., 2019) of the South Qiangtang Terrane and
258 the northern Indian margin of Gondwana (i.e., the Himalayas; Shellnutt et al., 2014)
259 indicate that the South Qiangtang Terrane was part of the northern Indian margin of
260 Gondwana during the Carboniferous–Early Permian (Zhang et al., 2012a; Zhu et al.,
261 2013; Metcalfe, 2013; Zhai et al., 2013; Liao et al., 2015; Chen et al., 2017).

262 Paleogeographic analysis indicates that the Indian margin of Gondwana was an
263 erosional zone, and the South Qiangtang Terrane was in a passive margin depositional
264 setting during the Late Carboniferous–Early Permian (Fan et al., 2015). The Indian

265 margin of Gondwana may therefore be the source of the Upper Carboniferous–Lower
266 Permian deposits in the South Qiangtang Terrane (Fan et al., 2015). The youngest
267 zircon age peak of ca. 550 Ma in the Upper Carboniferous–Lower Permian strata is
268 far older than the depositional age (ca. 300 Ma; Figs 4c–d), and thus provides strong
269 evidence for the stable Indian margin of Gondwana source.

270 The presence of abundant angular to subangular volcanic (e.g., basalts) and
271 sedimentary (e.g., limestones) lithic fragments in the Upper Permian sandstone of
272 the South Qiangtang Terrane (Figs 3d–e) indicate that their provenance lies in a
273 tectonically active rather than stable setting such as the Indian margin of
274 Gondwana. In addition, these samples plot in the recycled orogen sector in quartz–
275 feldspar–lithic fragment (QFL) and monocrystalline quartz–feldspar–total lithic
276 fragments (QmFLt) discrimination diagrams (Fig. 6). Moreover, many detrital
277 zircons in the Upper Permian sandstone of the South Qiangtang Terrane yield ages
278 (490–247 Ma) with peaks at ca. 460, 355, 290 and 260 Ma, which are not observed in
279 the age spectra of the Carboniferous–Lower Permian sandstones (Figs 4, 7). These
280 observations provide evidence that a significant sedimentary provenance change
281 occurred between the Carboniferous–Early Permian and the Late Permian in the
282 South Qiangtang Terrane.

283 Lithic fragments in the Upper Permian sandstone are mostly poorly sorted,
284 and are angular to subangular in shape (Figs 3d–e), indicating near-source
285 deposition. Lithic fragments in the Upper Permian sandstone in the Jiaco area are
286 dominated by limestone and basalt (Figs 3d–e), similar to that observed in the

287 rocks of the Lower–Middle Permian Lugu Formation in the South Qiangtang Terrane
288 (Fig. 2; Zhang et al., 2012a). Detrital zircons (299–285 Ma) in the Upper Permian
289 sandstone in the Ritu area mostly exhibit weak and broad zoning in CL images (Fig.
290 S1), and the detrital zircon grain with an age of 285 Ma has a $\epsilon_{\text{Hf}}(t)$ value of +6.9
291 (Table S5), both of which are similar to those of the 300–279 Ma mafic rocks (e.g.,
292 mafic dike swarms, +4.2 to +15.8; Fig. 1b; Zhai et al., 2013; Wang et al., 2019) in the
293 South Qiangtang Terrane. In the Upper Permian sandstone, the 490–445 Ma zircon
294 ages with a peak at ca. 460 Ma, and the 384–334 Ma zircon ages with a peak at ca.
295 355 Ma (Fig. 7) indicate Ordovician and Late Devonian–Early Carboniferous
296 magmatism occurred in the source region. This corresponds with the magmatism in
297 the South Qiangtang Terrane (Fig. 1b); for example, magmatism occurred at 500–450
298 Ma in a 300 km-long belt from Bensongco in the east to Dawashan in the west (Fig.
299 1b; Hu et al., 2015; Xie et al., 2017; Liu et al., 2019; Xu et al., 2020), and the 360–
300 350 Ma magmatism occurred in the Gangmuco area in the South Qiangtang Terrane
301 (Fig. 1b; Wang et al., 2015a). These observations, together with the basal
302 unconformity of the Upper Permian Jiapuria Formation (Fig. 2) that indicates uplift
303 and erosion of the South Qiangtang Terrane, provide strong evidence that the source
304 of the Upper Permian sandstone is derived from the erosion of sedimentary and
305 magmatic rocks in the South Qiangtang Terrane.

306 In conclusion, the source of the Upper Carboniferous–Lower Permian strata in
307 the South Qiangtang Terrane lies in the stable Indian margin of Gondwana, whereas
308 the Upper Permian strata are derived from the active South Qiangtang Terrane (Fig. 7).

309 The sedimentary provenance changed significantly between the Late Carboniferous–
310 Early Permian and Late Permian periods. The angular unconformity between the
311 Lower Permian Tunlonggongba and Upper Permian Jipuria formations in the Ritu
312 area (Fig. 2; Liang et al., 1983; Zhang et al., 2019) indicate that the western South
313 Qiangtang Terrane must have been uplifted after deposition of the Lower Permian
314 Tunlonggongba Formation, which marks the point at which the provenance changed
315 (Figs 2, 7). The same observations (Figs 2, 7) further suggest that the provenance
316 change may have started in the Early Permian (ca. 280 Ma), and continued into the
317 Middle Permian (273–260 Ma).

319 **5.3 Cause of the 280–260 Ma sedimentary provenance change in the South**

320 **Qiangtang Terrane**

321 The cause of the 280–260 Ma sedimentary provenance change in the South
322 Qiangtang Terrane is debated. Extensive magmatism occurred at 300–279 Ma in
323 South Qiangtang, Baoshan, Himalayas and Panjal along the northern Indian margin of
324 Gondwana, over an area greater than 2×10^6 km² (Zhai et al., 2013; Zhu et al., 2013;
325 Shellnutt et al., 2014; Liao et al., 2015; Wang et al., 2019). This magmatism is
326 characterised by mafic dike swarms and basalts (Zhai et al., 2013; Wang et al., 2014;
327 Fig. 1b). Whole-rock geochemical data indicate that the mafic dike swarms are
328 tholeiitic in composition, exhibit relative enrichment in light rare earth elements, and
329 have high Nb, Ta and Ti contents, which is typical of intra-plate basalts (Zhai et al.,
330 2013; Wang et al., 2014, 2019; Liao et al., 2015). They show consistently positive

331 $\epsilon\text{Nd}(t)$ (e.g., +2.3 to +7.6 in the South Qiangtang Terrane) and $\epsilon\text{Hf}(t)$ (e.g., +4.2 to
332 +15.8 in the South Qiangtang Terrane; Zhai et al., 2013; Wang et al., 2019) values.
333 These results indicate that the 300–279 Ma magmatism was most likely derived from
334 an enriched subcontinental lithospheric mantle source and triggered by the mantle
335 plume-induced rifting process occurring on the northern Indian margin of Gondwana
336 (Zhai et al., 2013; Wang et al., 2014, 2019; Liao et al., 2015).

337 The 280–260 Ma sedimentary provenance change in the South Qiangtang
338 Terrane closely follows the 300–279 Ma rift magmatism in time and space. We infer
339 that the 280–260 Ma sedimentary provenance change in the South Qiangtang Terrane
340 was caused by the widespread 300–279 Ma rift magmatism. This process resulted in
341 uplift of the northern Indian margin of Gondwana (e.g., the South Qiangtang) and a
342 change of depositional environment from marine to terrestrial at 280–260 Ma (Figs 2,
343 7). This uplift resulted in erosion of Ordovician, Late Devonian–Early Carboniferous
344 and Permian magmatic and sedimentary rocks, which changed the sedimentary
345 provenance signature of the area significantly.

346 The rifting magmatism at 300–279 Ma may represent the early stage of rifting,
347 and the 280–260 Ma sedimentary provenance change may represent the late stage (Fig.
348 8). The rifting magmatism and subsequent sedimentary provenance change represent
349 a complete Early–Middle Permian (300–260 Ma) rifting process on the northern
350 Indian margin of Gondwana.

351

352 5.4 Opening of the Meso-Tethys Ocean

353 The opening of the Meso-Tethys Ocean was genetically the rifting of the South
354 Qiangtang Terrane from the Indian margin of Gondwana (Yin and Harrison, 2000;
355 Metcalfe, 2013; Zhai et al., 2013; Liao et al., 2015; Chen et al., 2017). The Early–
356 Middle Permian (300–260 Ma) rifting process on the northern Indian margin of
357 Gondwana (eg., the South Qiangtang) may represent the initial opening of the
358 Meso-Tethys Ocean. This interpretation is also supported by the following three lines
359 of evidence.

360 (1) The parent material of the Late Carboniferous–Early Permian glacial marine
361 diamictites and sandstones (ca. 300 Ma) in the South Qiangtang Terrane was derived
362 directly from the Indian margin of Gondwana (Fig. 7; Fan et al., 2015). This indicates
363 that the South Qiangtang Terrane was still connected to the Indian margin of
364 Gondwana at least during the Late Carboniferous–Early Permian (ca. 300 Ma; Fig.
365 9a). The initial opening of the Meso-Tethys must have occurred after this time.

366 (2) The ages of the oldest MORB-type and OIB-type ophiolites in the BNSZ are
367 Late Permian–Early Triassic (260–250 Ma; Huang et al., 2012; Wang et al., 2015b;
368 Dong et al., 2016; Zhang et al., 2016, 2017) indicating that development of the
369 Meso-Tethys oceanic crust occurred during this period. The 300–279 Ma rifting
370 magmatism marks the early stage of the rifting process (Figs 8, 9b; Metcalfe, 2013;
371 Liao et al., 2015; Chen et al., 2017; Wang et al., 2019) and the 280–260 Ma
372 sedimentary provenance change marks the late stage (Figs 8, 9c). The 260–250 Ma
373 ophiolites in the BNSZ represent the oceanic crust after ocean opening (Figs 8, 9d).

374 From earliest to latest, the 300–279 Ma rift magmatism, 280–260 Ma sedimentary
375 provenance change, and 260–250 Ma ophiolites complete the geological record of the
376 rifting to opening process of the Meso-Tethys Ocean (Fig. 8), which provides strong
377 evidence that the Meso-Tethys Ocean opened during the Early–Middle Permian (300–
378 260 Ma).

379 (3) Previous paleontological studies have shown that a significant
380 paleobiogeographic change from a peri-Gondwanan to transitional affinity (the
381 Tethyan Cimmerian subregion) occurred in the South Qiangtang Terrane from the
382 Artinskian to the Kungurian (Zhang et al., 2012b, 2014; Shen et al., 2016). This
383 transition was the result of the effects of the northward drift of the South Qiangtang
384 Terrane (Zhang et al., 2012b), which provides further evidence that the opening of the
385 Meso-Tethys Ocean occurred during Early–Middle Permian (300–260 Ma).

387 6. Conclusions

388 (1) A significant change in sedimentary provenance occurred between 280–260
389 Ma in the South Qiangtang Terrane of the Tibetan Plateau.

390 (2) The 280–260 Ma provenance change is associated with the development of
391 the rift-related magmatism at 300–279 Ma on the northern Indian margin of
392 Gondwana (e.g., South Qiangtang).

393 (3) The 300–279 Ma magmatism and the subsequent 280–260 Ma sedimentary
394 provenance change represent a complete Early–Middle Permian (300–260 Ma) rifting
395 process, which marks the opening of the Meso-Tethys Ocean.

396

397 **Acknowledgments**

398 We sincerely thank Xiao-Wen Zeng, Hang Li, Hao Wu, and Yun-Peng Yu for the help
399 in the field. This research was supported by the Second Tibetan Plateau Scientific
400 Expedition and Research (STEP) Program (Grant No. 2019QZKK0705), the National
401 Science Foundation of China (Grant No. 41972236, 41702227), and Self-determined
402 Foundation of Key Laboratory of Mineral Resources Evaluation in Northeast Asia,
403 Ministry of Natural Resources of China (DBY-ZZ-18-04). All data are provided in the
404 present manuscript and supporting information. The latter includes Figures S1-2 and
405 Tables S1-5 and is available at <https://zenodo.org/deposit/3754981> (DOI:
406 10.5281/zenodo.3754981). The data archiving process is underway awaiting approval
407 of the curator.
